Academy of Sciences, January 14.—M. Fizeau in the chair. —The following papers were read:—On the presence of oxygen in metallic silver, by M. Dumas. He shows that in the numerous experiments where silver has been used in determination of equivalents, the chemists who, after careful purification, converted it into minute grains after fusion in presence of borax, nitre, and air, have made it liable to absorb oxygen varying from 50 to 200 cubic centimetres per kilogramme. Hence much discrepancy.—On the formation of oxygenated water, ozone, and persulphuric acid during electrolysis, by M. Berthelot. The oxidising substance formed in electrolysis of sulphuric solutions is not oxygenated water, as commonly supposed, nor ozone in simple solution, but (as proved by the fact of its not being formed in other solutions, and by its reactions positive and negative) persulphuric acid. It is formed with absorption of heat. The three substances named may be simultaneously formed in electrolysis. The ozone may be changed into oxygenated water by means of ether; the oxygenated water may be changed into persulphuric acid by concentrated sulphuric acid; and persulphuric acid liberates gradually in the cold state the whole of its oxygen at the ordinary state without presenting any finite tension of dissociation.—On the stability of ozone, by M. Berthelot.—Experimental researches on the fractures traversing the earth's crust, especially those known as joints and faults, by M. Daubrée. One end of a long rectangular plate of the substance to be examined was seized between wooden jaws, and the other end by a wrench which gave torsion. The nature of the fractures (in gypsum and glass) are described; geological deductions will follow in another paper.—On the recent tornado of Ercildoun (Chester Co., Pennsylvania), by M. Faye. He finds evidence in it that these great gyratory movements arise in the upper currents and travel with them; they are propagated downwards to the ground.—On a new bed of Adamine by M. De Cloizeaux. This hydrated arseniate of zinc, found previously only at Chanarcillo, Chili, and in a mine of the Garonne, has now been found among the zinc ores of Laurium.—Note on the official report of last *séance*, by M. Pasteur.—The vibrations of matter and waves of ether; probable consequences of the fact which serves as base of the mechanical theory of heat, by M. Favé. *Inter alia*, the author gives an interpretation of the law of radiation and absorption, slightly differing from that given by Prof. Stokes.—On the liquefaction of gases, by M. Cailletet. Inclosing in the glass tube dry air freed from carbonic acid, he cooled with protoxide of nitrogen the upper part of the tube only. When the pressure was 200 atmospheres, streams of liquid (air) were seen flowing down the lower parts. When they met the mercury they seemed to turn back. At 310 atmospheres, the mercury being in contact with the cooled part of the tube, was frozen, and on quickly removing the refrigerating apparatus it was seen to be covered with what was probably *frozen air.*—Observations of the solar protuberances during the first six months of 1877, by P. Secchi. The figures are simply tabulated.—P. Secchi presented a copy of his new work (in Italian) entitled "The Stars; Essay in Sidereal Astronomy."—On telephony, by M. Breguet. The variations in conductivity of retort carbon have been utilised by M. Salet in a similar way to that of MM. Garnier and Pollard (see last week's report) with graphite, and with better results.—Study of the ultra violet solar spectrum, by M. Cornu. The first part of the memoir presented treats of the ultra violet spectrum from the line *h'* to the line O, observed with ordinary spectroscopes having glass objectives and prisms; the second part, from O to U, the ultra violet extremity observed photographically with a spectroscope with objectives of quartz and prism of Iceland spar. The limitation of the ultra violet spectrum is found to be caused by, and to vary with, the aqueous vapour in the atmosphere. The *maxima maximorum* of extent is at the summer solstice; but with equal height of the sun the spectrum is incomparably more extensive in winter than in summer.—On the fertility of volcanic soils, by M. Truchot. Phosphoric acid is the chief element of it.—Liquefaction of hydrogen, by M. Pictet.—On the question of the special conditions of contour of elastic plates, by M. Boussinesq.—On an industrial application of Gauss's theorem regarding the curvature of surfaces, by M. Levy.—On the function arising from development of the expression $(1 - 2ax + a^2a^2)^{\frac{-2l+1}{2}}$, by M. Escary. —On a theorem of M. Chasles, by M. Serret.—On the function of Jacob Bernouilli and on the interpolation, by M. Lipschitz.—On the preparation of curare, by M. Jobert.—Palæontological contributions, by M. Meunier.—Effect of a low temperature on a mixture of oxygenated water and sulphuric acid, by M. Boillot.

TAIT'S "THERMODYNAMICS"

Sketch of Thermodynamics. By P. G. Tait, M.A., formerly Fellow of St. Peter's College, Cambridge, Professor of Natural Philosophy in the University of Edinburgh. Second Edition, revised and extended. (Edinburgh: David Douglas, 1877.)

THIS book, as we are told in the preface, has grown out of two articles contributed in 1864 by Prof. Tait to the *North British Review*. This journal, about that time, inserted a good many articles in which scientific subjects were discussed in scientific language, and in which, instead of the usual attempts to conciliate the unscientific reader by a series of relapses into irrelevant and incoherent writing, his attention was maintained by awakening a genuine interest in the subject.

The attempt was so far successful that the publishers of the *Review* were urged by men of science, especially engineers, to reprint these essays of Prof. Tait, but the *Review* itself soon afterwards became extinct.

Prof. Tait added to the two essays a mathematical sketch of the fundamental principles of thermodynamics, and in this form the book was published in 1868. In the present edition, though there are many additions and improvements, the form of the book is essentially the same.

Whether on account of these external circumstances, or from internal causes, it is impossible to compare this book either with so-called popular treatises or with those of a more technical kind.

In the popular treatise, whatever shreds of the science are allowed to appear, are exhibited in an exceedingly diffuse and attenuated form, apparently with the hope that the mental faculties of the reader, though they would reject any stronger food, may insensibly become saturated with scientific phraseology, provided it is diluted with a sufficient quantity of more familiar language. In this way, by simple reading, the student may become possessed of the phrases of the science without having been put to the trouble of thinking a single thought about it. The loss implied in such an acquisition can be estimated only by those who have been compelled to unlearn a science that they might at length begin to learn it.

The technical treatises do less harm, for no one ever reads them except under compulsion. From the establishment of the general equations to the end of the book, every page is full of symbols with indices and suffixes, so that there is not a paragraph of plain English on which the eye may rest.

Prof. Tait has not adopted either of these methods. He serves up his strong meat for grown men at the beginning of the book, without thinking it necessary to employ the language either of the nursery or of the school; while for younger students he has carefully boiled down the mathematical elements into the most concentrated form, and has placed the result at the end as a *bonne bouche*, so that the beginner may take it in all at once, and ruminate upon it at his leisure.

A considerable part of the book is devoted to the history of thermodynamics, and here it is evident that with Prof. Tait the names of the founders of his science call up the ideas, not so much of the scientific documents they have left behind them in our libraries, as of the men themselves, whether he recommends them to our reverence as masters in science, or bids us beware of them as tainted with error. There is no need of a garnish of anecdotes to enliven the dryness of science, for science has enough to do to restrain the strong human nature of the author, who is at no pains to conceal his own idiosyncrasies, or to smooth down the obtrusive antinomies of a vigorous mind into the featureless consistency of a conventional philosopher.

Thus, in the very first page of the book, he denounces all metaphysical methods of constructing physical science, and especially any *à priori* decisions as to what may have been or ought to have been. In the second page he does not indeed give us Aristotle's ten categories, but he lays down four of his own:—matter, force, position, and motion, to one of which he tells us, "it is evident that every distinct physical conception must be referred," and then before we have finished the page we are assured that heat does not belong to any of these four categories, but to a fifth, called energy.

This sort of writing, however unlike what we might expect from the conventional man of science, is the very thing to rouse the placid reader, and startle his thinking powers into action.

Prof. Tait next handles the caloric theory, but instead of merely showing up its weak points and then dismissing it with contempt, he puts fresh life into it by giving (in the new edition) a characteristic extract from Dr. Black's lectures, and proceeds to help the calorists out of some of their difficulties, by generously making over to them some excellent hints of his own.

The history of thermodynamics has an especial interest as the development of a science, within a short time and by a small number of men, from the condition of a vague anticipation of nature to that of a science with secure foundations, clear definitions, and distinct boundaries.

The earlier part of the history has already provoked a sufficient amount of discussion. We shall therefore confine our remarks to the methods employed for the advancement of the science by the three men who brought the theory to maturity.

Of the three founders of theoretical thermodynamics, Rankine availed himself to the greatest extent of the scientific use of the imagination. His imagination, however, though amply luxuriant, was strictly scientific. Whatever he imagined about molecular vortices, with their nuclei and atmospheres, was so clearly imaged in his mind's eye, that he, as a practical engineer, could see how it would work.

However intricate, therefore, the machinery might be which he imagined to exist in the minute parts of bodies, there was no danger of his going on to explain natural phenomena by any mode of action of this machinery which was not consistent with the general laws of mechanism. Hence, though the construction and distribution of his vortices may seem to us as complicated and arbitrary as the Cartesian system, his final deductions are simple, necessary, and consistent with facts.

Certain phenomena were to be explained. Rankine set himself to imagine the mechanism by which they might be produced. Being an accomplished engineer, he succeeded in specifying a particular arrangement of mechanism competent to do the work, and also in predicting other properties of the mechanism which were afterwards found to be consistent with observed facts.

As long as the training of the naturalist enables him to trace the action only of particular material systems without giving him the power of dealing with the general properties of all such systems, he must proceed by the method so often described in histories of science—he must imagine model after model of hypothetical apparatus till he finds one which will do the required work. If this apparatus should afterwards be found capable of accounting for many of the known phenomena, and not demonstrably inconsistent with any of them, he is strongly tempted to conclude that his hypothesis is a fact, at least until an equally good rival hypothesis has been invented. Thus Rankine,[1] long after an explanation of the properties of gases had been founded on the theory of the collisions of molecules, published what he supposed to be a proof that the phenomena of heat were invariably due to steady closed streams of continuous fluid matter.

The scientific career of Rankine was marked by the gradual development of a singular power of bringing the most difficult investigations within the range of elementary methods. In his earlier papers, indeed, he appears as if battling with chaos, as he swims, or sinks, or wades, or creeps, or flies,

> "And through the palpable obscure finds out
> His uncouth way;"

but he soon begins to pave a broad and beaten way over the dark abyss, and his latest writings show such a power of bridging over the difficulties of science, that his premature death must have been almost as great a loss to the diffusion of science as it was to its advancement.

The chapter on thermodynamics in his book on the steam-engine was the first published treatise on the subject, and is the only expression of his views addressed directly to students.

In this book he has disencumbered himself to a great extent of the hypothesis of molecular vortices, and builds principally on observed facts, though he, in common with Clausius, makes several assumptions, some expressed as axioms, others implied in definitions, which seem to us anything but self-evident. As an example of Rankine's best style we may take the following definition:—

> "A PERFECT GAS is a substance in such a condition that the total pressure exerted by any number of portions of it, at a given temperature, against the sides of a vessel in which they are inclosed, is the sum of the pressures which each portion would exert if inclosed in the vessel separately at the same temperature."

Here we can form a distinct conception of every clause of the definition, but when we come to Rankine's Second Law of Thermodynamics we find that though, as to literary form, it seems cast in the same mould, its actual meaning is inscrutable.

> "*The Second Law of Thermodynamics.*—If the total actual heat of a homogeneous and uniformly hot substance be conceived to be divided into any number of equal parts, the effects of those parts in causing work to be performed are equal."

We find it difficult enough, even in 1878, to attach any distinct meaning to the total actual heat of a body, and still more to conceive this heat divided into equal parts, and to study the action of each of these parts, but as if our powers of deglutition were not yet sufficiently strained, Rankine follows this up with another statement of the same law, in which we have to assert our intuitive belief that—

> "If the absolute temperature of any uniformly hot substance be divided into any number of equal parts, the effects of those parts in causing work to be performed are equal."

The student who thinks that he can form any idea of the meaning of this sentence is quite capable of explaining on thermodynamical principles what Mr. Tennyson says of the great Duke:—

> "Whose eighty winters freeze with one rebuke
> All great self-seekers trampling on the right."

Prof. Clausius does not ask us to believe quite so much about the heat in hot bodies. In his first memoir, indeed, he boldly dismisses one supposed variety of heat from the science. Latent heat, he tells us, "is not only, as its name imports, hidden from our perceptions, but has actually no existence;" "it has been converted into work."

But though Clausius thus gets rid of all the heat which, after entering a body, is expended in doing work, either exterior or interior, he allows a certain quantity to remain in the body as heat, and this remnant of what should have been utterly destroyed lives on in a sort of smouldering existence, breaking out now and then with just enough vigour to mar the scientific coherence of what might have been a well compacted system of thermodynamics.

Prof. Tait tells us:—

> "The source of all this sort of speculation, which is as old as the time of Crawford and Irvine—and which was countenanced to a certain extent even by Rankine—is the assumption that bodies must contain a certain quantity of actual, or thermometric, heat. We are quite ignorant of the condition of energy in bodies generally. We know how much goes in, and how much comes out, and we know whether at entrance or exit it is in the form of heat or of work. But that is all."

If we define thermodynamics, as I think we may now do, as the investigation of the dynamical and thermal properties of bodies, deduced entirely from what are called the First and Second laws of Thermodynamics, without any hypotheses as to the molecular constitution of bodies, all speculations as to how much of the energy in a body is in the form of heat are quite out of place.

Prof. Tait, however, does not seem to have noticed that Prof. Clausius, in a footnote to his sixth memoir,[1] tells us what he means by the heat in a body. In the middle of a sentence we read:—

> ". . . . the heat actually present in a unit weight of the substance in question—in other words, the *vis viva* of its molecular motions" . . . .

Thus the doctrine that heat consists of the *vis viva* of molecular motions, and that it does not include the potential energy of molecular configuration—the most important doctrine, if true, in molecular science—is introduced in a footnote under cover of the unpretending German abbreviation "d.h."

(*To be continued.*)

WOLF'S HISTORY OF ASTRONOMY

Geschichte der Astronomie. Von Rudolf Wolf. (München: R. Oldenbourg, 1877.)

THE "History of Astronomy," by Prof. Rudolf Wolf, of Zurich, a volume of 800 pages issued at a very moderate figure, is a contribution to the literature of the science of no ordinary value to the student. The production of such a work, involving an outline of the progress of astronomy from the earliest times to the present period, must have been a labour of great extent, requiring much research, notwithstanding the assistance that might be afforded by historical treatises previously in the hands of astronomers, and it is only due to Prof. Wolf to acknowledge the very able and complete manner in which he has accomplished the heavy task he had imposed upon himself some years since.

Those of our readers who may have been desirous of acquainting themselves with the general history of practical astronomy, and of familiarising themselves with the names and the nature of the services of the principal workers who have successively contributed to advance our knowledge of the science, more especially during the last three centuries, will, we think, have experienced difficulties which the volume before us is well calculated to obviate. The English reader has, it is true, Prof. Grant's classical work, the "History of Physical Astronomy," but there is much to be found in this volume, which it was hardly within the scope of Prof. Grant's work to incorporate. The writer of these lines very well remembers the fragmentary manner in which, some thirty-five years since, an English student of practical astronomy was under the necessity of obtaining information, more especially in private reading; and it is one of the most happy circumstances for the astronomical student of the present day that this want of suitable guides has been to a great extent removed, and his time therefore need not be wasted in a search for knowledge in second-rate or doubtful authorities, mistakes which he would be not infrequently led into thereby, being corrected only after vexatious delay and trouble.

Prof. Wolf divides his work into three books. The first deals with ancient astronomy and progress down to the fifteenth century, including theories, instruments, and writings. The second commences with "the reformation of astronomy" consequent on the publication of the great work of Copernicus, "De Revolutionibus Orbium Cœlestium," and treats of the advances made to the time of Newton; we find therefore in this division a summary of the labours of Galileo, Apian, Tycho Brahe, Kepler, Fabricius, Harriot, Hevelius, Huyghens, Gascoigne, and many others, including notices of the more important publications of the period, which are of interest and value. The third book treats of "the new astronomy," commencing with the discovery of universal gravitation and brings down the history of astronomical research and discovery to the present epoch. A very great amount of information is compressed into this last section of the work, and it is here that the care and research of the author are more particularly evidenced. There is much to be found in it, for which we should look in vain in a collective and compendious form elsewhere. It is well and accurately put together, the few errors we have remarked being of comparatively trifling nature; thus the Saturnian satellite *Tethys* appears as *Thetis.* The biographical notes, which are extended to contemporary astronomers, will be a welcome feature to many readers.

Students and others interested in the history of the most ancient of the sciences, who can command a sufficient knowledge of the German language, will find their advantage in the possession of Prof. Wolf's elaborate work, and we must not omit to say that that great desideratum in all works of the kind—a very sufficient index, at least as regards names mentioned in the history, will render it of easy reference.

J. R. HIND

(*To be continued.*)

OUR BOOK SHELF

Photographic Spectra. 136 *Photographs of Metallic, Gaseous, and other Spectra printed by the Permanent Autotype Process.* With Introduction, Description, &c., by J. R. Capron, F.R.A.S. (E. and F. N. Spon.)

WE gather from the author's introduction that he has chiefly aimed "to popularise a subject hitherto somewhat of a sealed book, confined to the laboratories of workers in special research." In this he should certainly succeed, though we think that his readers would not have been driven away if they had found a little more reference to the explanations of the various phenomena and the conclusions which have been drawn from them. As it is, the book is a good companion to Lecoq de Boisbaudran's "Spectres Lumineux." The spectra are sharp and clear, and the autotype process has lent itself well to this reproduction. The results are all the more commendable because Mr. Capron has not had the advantages of considerable dispersion.

The account of the method employed is full and clear, and will make the book a very useful one to beginners in spectrography.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Sun-spots and Terrestrial Magnetism

PROF. PIAZZI SMYTH will no doubt welcome from any quarter a satisfactory answer to his question about the discrepancy between Dr. Wolf's sun-spot period, 11·1 years, and the supposed 10·5 years' period for the magnetic needle. If Mr. Smyth will refer to Prof. Loomis's chart of magnetic oscillations given in Prof. Balfour Stewart's paper on the subject in NATURE (vol. xvi. p. 10), he will see that there are exactly seven minimum-periods from 1787 to 1871, the mean of which is twelve years; the mean of the seven corresponding maximum-periods is 11·8 years. The true magnetic declination-period is then the mean of these, viz., 11·9 years. In exactly the same manner I have found that the mean period of sun-spots is 11·9 years. The auroral displays also have the same period.

But what is this period of 11·9 years? It is Jupiter's anomalistic year, or the time which elapses between two perihelion passages.

Prof. Wolf and Messrs. De la Rue, Stewart, and Loewy have all distinctly stated their belief that Jupiter is the chief cause in the production of sun-spots. This 11·9 years' period will then, I believe, remove what little doubt remains in some minds on the subject. Mr. John Allan Broun, F.R.S., has already shown in NATURE (vol. xvi. p. 62) that Dr. Wolf, to be consistent with his own relative numbers, ought to take a period of 11·94 years rather than one of 11·1, and while he himself favours a 10·5 years' period, he admits that there is no combination of planetary positions which would produce such.

I may perhaps be allowed to state here that in a paper I have just forwarded to the Royal Astronomical Society I have given what I believe are satisfactory reasons for the variations of these curves, and such as will enable us for the future to calculate with considerable accuracy the lengths of the periods, and guided by these reasons I have ventured to state my belief that we are now passing through a long minimum-period—one very similar to that which occurred at the close of the last century, and that the next *maximum* of sun-spots will fall in the year 1887.

I make this statement from an examination of the causes which produce the sun-spots; and it is so far remarkably confirmed by the behaviour of the magnetic needle. Mr. Broun, in NATURE, vol. xvii. p. 183, speaking of the very gradual manner in which the curve has been going to a minimum during the last three and a half years, remarks that "no such constant state of the sun's magnetic action will have been observed since the last years of the eighteenth century." To this I would add that immediately prior to the commencement of that long sun-spot minimum period, the mean of the magnetic interval, which occurred then (reckoning the interval from minimum to maximum), fell in the year 1785, and corresponded with the time of Jupiter's perihelion passage. Suppose now we represent this synchronism by 0, it will be found that the mean point in the next period lagged behind the perihelion 1·6 year; next, 5·3 years; next, 5·3 years. Having reached its maximum of lagging, in the next period it lagged 3·9 years; next, 1·2 year; next, 0·6 year; and in the last period the mean point fell in the year 1868, coinciding for the first time since 1785 with Jupiter's perihelion, and will be represented by 0. So that the magnetic oscillation in 1868 was just where it was in 1785. Is it not a natural inference, then, that we have commenced another cycle of magnetic declination?

What produces this lagging? This is a very important question, and one which I have reason to believe can be satisfactorily answered. B. G. JENKINS

January 19

On a Means for Converting the Heat Motion Possessed by Matter at Normal Temperature into Work

MY attention has just been directed to Mr. S. Tolver Preston's two papers in NATURE, vol. xvii. p. 31 and p. 202, in which he points out what appears to be an exception to the second law of thermodynamics. Some years ago I illustrated the same subject in a somewhat different manner by an experiment which is in some respects better suited for lecture purposes, and while the subject is being considered may be useful to your readers.

Into the cork of a large bottle were fitted two glass tubes. One tube went to the bottom of the bottle, its upper end being terminated in a fine jet. The other tube only passed a short distance into the bottle, and its upper end terminated about an inch above the cork. To its lower end was fixed some pieces of blotting-paper, to its upper end was attached a small test-tube, the two being connected by means of a piece of india-rubber tube. Some water was put in the bottle and the cork fitted close in its place. The test-tube was then filled with ether or some volatile fluid, and fitted to the end of the india-rubber tube.

After the apparatus had attained a uniform temperature, the test-tube was inverted, so as to cause the ether to flow down the tube, and enter the bottle, where it spread itself over the blotting paper and, rapidly evaporating, produced a pressure inside the bottle. The addition of the ether vapour to the air already at atmospheric pressure, produced a pressure sufficient to force the water up the tube and out of the jet, causing it to rise to a considerable height into the air. At the beginning of the experiment all the apparatus was at a uniform temperature, and, according to the generally received opinion, ought to have been incapable of developing energy, yet on account of the ether vapour not being diffused through the system, it was able to do work at the expense of part of the heat in the system. JOHN AITKEN

Darroch, Falkirk, January 18

No Butterflies in Iceland

ALLOW me to point out that the lepidopterous insects said by Olafsen (not Olaffson) and N. (not K.) Mohr, to be found in Iceland, are not butterflies at all, but moths, as shown by the generic term *Phalæna* applied by each of those authors to every one of them—a term whose meaning your correspondent and his informant have failed to see. Those venerable authors, though dead and buried long before I ever heard of them, are old friends of mine, and I feel it incumbent on me to ask your readers not to impute to them this and other mistakes in Dr. Rae's letter. Whether there have been or still be butterflies in Iceland I am not competent to declare. I did not see any when I was there, but they may have got out of my way. I have, however, yet to learn that they exist in that country, and therefore I am inclined to believe Mr. McLachlan is right when he said that there are none. We have the testimony of the late Sir William Hooker ("Tour," &c., ed. 2, vol. i p. 333) that no butterfly had ever been met with in Iceland up to 1809, the year in which he visited that island. Gliemann ("Geogr. Beschreib. Isl.," p. 165) in 1824 was unable to add to Mohr's list of twelve species of moths, and included no butterflies. If any of the latter have since been found it would be well for Dr. Rae to give his authority for the fact, otherwise his ingenious supposition that Icelandic butterflies and their larvæ have been destroyed since 1786, is unnecessary, and his "only possible way" of reconciling "perfectly opposite authorities" falls to the ground through the absence of any opposition on the part of the authorities he has cited. ALFRED NEWTON

Magdalene College, Cambridge, January 25

[Dr. Rae writes "to explain and correct a mistake which, by a little care and attention on my part could and should have been so easily avoided."]

On some Peculiar Points in the Insect-Fauna of Chili

MY friend Mr. Birchall misconstrued the meaning of my notes (NATURE, vol. xvii. p. 162) in a manner incomprehensible to me, when penning his own (p. 221). I, and many others, will share his "surprise" when he can produce any species of the genera *Carabus*, *Argynnis*, and *Colias*, or any of the *Limnophilidæ* from Australia or New Zealand. If he will do me the favour to again read my notes he will find that I refer solely to Palæarctic and Nearctic forms occurring in the Chilian subregion and (unless by exception) nowhere else in the southern hemisphere.

Mr. Wallace's rebuke (p. 182) is to some extent merited. I *did not* give sufficient attention to the chapter in his work, to which he refers, in consequence of its *general* character. Mr. Wallace greatly extends the number of genera published by me as a sample. Some of these were perfectly familiar to me; others, I think, will fail to stand the test of minute application, partly because their distribution is more extended, partly because generic definitions are vague. I could add several interesting and marked genera. *Colias* may possibly be represented by more than one species on the Northern Andes; but it is the opinion of naturalists who, from practical acquaintance with the fauna of South America, and who, on a special point like this, are more competent than I to judge, that most of the very marked forms upon which I especially rely *do not* occur on the Northern Andes, which of late have been most assiduously worked by entomologists hunting insects for sale and perfectly alive to the value of such forms.

Mr. Darwin's theory alluded to by Mr. Birchall had not been overlooked. I was dealing with insects, and with a few marked genera, &c., of them, only. In plants there appears to be a tendency towards the appearance of analogous or identical forms all over the world when a sufficient altitude (varying according to the latitude) is reached. The laws that govern the distribution of the one ought equally to affect the other. Still the facts alluded to in my former letter remain unexplained. The southern portion of South America forms, as it were, an island, with a large admixture of Palæarctic and Nearctic faunistic elements existing in no other part of the southern hemisphere.

Lewish[illegible], January 19 ROBERT MCLACHLAN

The Radiometer and its Lessons

PROF. OSBORNE REYNOLDS arranges his last letter (NATURE, vol. xvii. p. 220) under four numbered heads, and in the reply which I appear called on to make I will follow this division.

1. In the first section he says, "There is nothing in my earlier papers that is 'admittedly erroneous.' If there is error in these papers I am not aware of it." This is strange. In his first paper (*Proceedings*, Royal Society, vol. xxii. p. 40) Prof. Reynolds declares its object to be "to point out and to describe experiments to prove that these effects (the motions observed by Mr. Crookes) are the results of evaporation and condensation." Now they are not the results of evaporation and condensation: and it might have been seen, *ab initio*, that evaporation and condensation could have had nothing to do with them; for evaporation and condensation can only produce a temporary force, ceasing so soon as the distillation is complete, and cannot therefore be any part of the cause of a persistent force such as that detected by Mr. Crookes, which lasts for any length of time during which the heat is applied. In the same paper Prof. Reynolds further says, "The reason why Mr. Crookes did not obtain the same results within a less perfect vacuum [than that of the Sprengel pump], was because he had then too large a proportion of air, or non-condensing gas, mixed with the vapour, which was also not in a state of saturation." All this is manifest error. But this is not all, for *the whole of the theory* of those papers is erroneous; neither condensable vapour nor residual gas acts in the way described by Prof. Osborne Reynolds. In investigating the force arising from evaporation and condensation, he has overlooked the circumstance that the evaporation from the disc will keep back part of the vapour which would otherwise have reached it, and in investigating the effect of condensation he tacitly assumes that it does keep it back. Now in both cases the reverse of the assumption is what takes place, and he actually arrives at the absurd result that "if the opposite sides of a pith ball in vapour were in such different conditions [*i.e.*, one surface evaporating, the other condensing] the ball would be forced towards the colder side" (p. 404). His conclusion amounts to this: that the recoil of a cannon would be doubled if it were struck from behind by a missile at the same moment that it discharges an equal mass with equal velocity forwards! If he had not made these mistakes he would have got out only the forces which result from "the perceptible motion of the vapour," which he states "would be insensible" (p. 403), along with alterations in the general tension of the vapour *which would act equally on both sides of the disc*. Those errors vitiate the whole of his mathematical reasoning, so that the value for f which he gets, is not, as he supposes, "the force arising from evaporation," and his law connecting it with the heat falls to the ground. I have all along supposed, from Prof. Reynolds's having long ceased to mention his theory of evaporation and condensation, that he was aware of some of its errors.

The same error vitiates his reasoning in reference to the action of residual gas. If the error is corrected, and if, as he assumes, the gas coming up to the disc had been unpolarised (*i.e.* had brought to the disc equal numbers of molecules, and with equal velocities from all directions in front), his investigation *would only have given him an increase in the general pressure of the gas*, acting, as I pointed out in paragraph 5 of my first paper (*Phil. Mag.*, March, 1876, p. 179), equally on the front and back of the disc, except during the almost inappreciable instant of adjustment. *Prof. Osborne Reynolds therefore wholly missed the source of the persistent force with which Mr. Crookes's experiments deal.*

2. Prof. Osborne Reynolds next says that his second paper "does not conclude with his own expression of opinion that residual gas is not the cause of the force observed by Mr. Crookes." In reply I have only to quote the concluding words of that paper (*Phil. Mag.*, November, 1874, p. 391). After passing under review the two agencies (condensable vapour and residual gas), which he supposes are to be considered, he decides in favour of the former in the following words: "hence in such cases [*i.e.*, under the conditions which he supposed to prevail in Mr. Crookes's experiments] it seems to me that the effects must be due to the forces of condensation."

3. In the next section of his letter Prof. Reynolds states that Clausius and Maxwell "established the law that the only condition of thermal equilibrium in a gas is that of uniform temperature." I am not aware that they have ever established this law. The converse of it is obviously true, and has often been used, and the law itself has sometimes been assumed, but has never, so far as I know, been proved. I am, however, disposed to concur with those who think that it is probably true, and the conclusion in my paper on penetration (which is the reverse of that attributed to me by Prof. Reynolds) is in conformity with it. My conclusion is expressed in the following words (*Phil. Mag.*, December, 1877, § 4):—"Hence there must, in the cases that really arise, be some escape of heat which may be small but cannot vanish." And, I may remark, there will, according to my view, be two other sources of escape of heat, viz., conduction by diffusion, which was excluded from my investigation; and conduction by radiation, which was excluded both from Clausius's investigation (*Phil. Mag.*, June, 1862, p. 422, footnote) and from mine.

Prof. Osborne Reynolds a second time objects to my having excluded conduction when investigating the penetration of heat. As he attaches weight to authority he will perhaps be reconciled to my doing so, by the example of Clausius, as cited above, and by his justification of it in the following words (*loc. cit.*):—"In any case, however, it is allowable to consider separately each of these two ways in which heat moves."

Before passing from this subject I wish to take the opportunity of stating that Dr. Schuster's letter (NATURE, vol. xvii. p. 143) has satisfied me that I have hitherto erred in my estimate of the relative efficiency of penetration and conduction as agents for conveying heat. I am now convinced that penetration is usually feeble compared with conduction, and, in the figures representing De la Prevostaye and Desains' experiments, is to be sought in those portions of the curves which slope steeply downwards. The second part of my paper on penetration, that in which I apply the theory to experiment, will accordingly require considerable modification; and some of the statements which I made in my papers on Crookes's force will need amendment. The corrections that are required do not, however, affect any of the material parts of my theories of Crookes's force and of penetration, which depend essentially on the fact that there is a layer in the gas extending to a limited distance from a heater or cooler, throughout which the effects of the discontinuity in the gaseous motions at the surface will be felt, and that within that layer the stresses and the communication of heat follow special laws.

4. I have to express my great satisfaction at the explicit admission made by Prof. Osborne Reynolds in the fourth section of his letter, in the following sentences:—"There is one statement in Mr. Stoney's letter which is not erroneous. He says, 'I cannot find anywhere in Prof. Osborne Reynolds's writings an explanation of the thing to be explained, viz., that the stress in a Crookes's layer is different in one direction from what it is at right angles to that direction.' I [Prof. Osborne Reynolds] do not at all admit that this is 'the thing to be explained,' and I am quite sure that Mr. Stoney would find no explanation of it in my writings." This admission disposes finally of all controversy as to priority between us.

I need hardly, after this admission, follow Prof. Osborne Reynolds through the rest of his letter. His supposed invariable law "that the [Crookes's] force always tends to drive the vanes or bodies in the direction of their colder faces," does not seem to be true. A familar exception occurs when a spheroidal drop is supported over a platinum dish. The Crookes's force acting upon the platinum dish is equal to the weight of the drop, and acts downwards, *i.e.* in the direction of the *hottest* surface of the dish.

In applying his hypothetical case of a heater and cooler, A and B, within an envelope of intermediate temperature, to prove that "the force that causes the motion in the bodies cannot be due" to the stresses of my theory, he has overlooked the very obvious circumstance that the envelope, as well as B, is a cooler in reference to A, and the envelope, as well as A, is a heater in reference to B.

Prof. Reynolds observes that I have not defined polarisation. I described the kind of polarisation that exists in radiometers in my first two papers, and I will give a formal definition of the term as applied generally to gases in an article which I am preparing, and which I hope will be admitted into the pages of NATURE, giving as clear an account of my theory as I can, compatibly with brevity and the omission of mathematics.

The way in which Prof. Reynolds has excluded polarisation from his explanation is by assuming that the state of the gas close to the heated disc may be adequately represented by unpolarised gas of one temperature coming up to the disk, and unpolarised gas of another temperature leaving it, *i.e.*, by molecules coming up to the heater in equal numbers and with equal velocities from *all* directions in front, and by molecules receding from the heater equally in all directions, although with augmented velocities. Under these circumstances there would be no difference in the pressure on the front and back of the disc, except during the very brief period of adjustment.

By making this assumption Prof. Reynolds leaves the part of Hamlet out of the play; for Crookes's force arises out of the very circumstance which has been omitted, viz., that the molecules that come up to the heater or cooler, arrive in the form of a rain which predominates in a definite direction, a direction which is normal to the heater and cooler in the simple case of their being parallel. G. JOHNSTONE STONEY

A Double Rainbow

ON the 28th inst., at about 6.30 P.M. while myself and some ten or twelve other gentlemen were playing cricket, we were surprised to see what we all considered a most novel phenomenon—*a double rainbow.* The sky was cloudy and the weather was thundery. At the time referred to a shower of rain fell; the sun was about 10° above the horizon, shining out very brilliantly and reflecting upon the waters of St. Vincent's Gulf. Great wonder was expressed at the strange appearance, and much curiosity as to the cause.

The appearance was as follows:—There were two distinct and well-defined bows; the feet were united, but the apices were a considerable distance apart.

I am of opinion that the lower bow was caused by the direct light of the sun, while the light reflected from the sea produced the upper one. THOMAS NOYÉ

Willunga, South Australia, November 30

SCIENCE IN TRAINING COLLEGES

THE Science and Art Department has just issued a circular having an important bearing on the teaching of science is to take in our training colleges, and therefore also in elementary schools.

The Lords of the Committee of Council on Education believe that the time has arrived when a special examination should be instituted at a period of the year better adapted to the training colleges than May, and that the nature of the examination and the payments made on the results should be modified to suit the circumstances of those colleges. They have therefore determined that in future a special examination in science shall be held in training colleges in December, immediately before the ordinary Christmas examination.

The examination will not be open to acting teachers. It will be held in those subjects only for which a special course of instruction is provided in the time-table of the College, and will be conducted by one of her Majesty's inspectors or by an officer of the Science and Art Department. Special committees will no longer be required for the training colleges; such returns as are necessary will be made by the principal. No student in a training college will be allowed to attend the May examinations of the Science and Art Department, except in physical geography in May, 1878.

The examination will be confined to the following nine subjects:—1. Mathematics. 2. Theoretical Mechanics. 3. Applied Mechanics. 4. Acoustics, Light, and Heat. 5. Magnetism and Electricity. 6. Inorganic Chemistry, including Practical Chemistry. 7. Animal Physiology. 8. Elementary Botany. 9. Physiography.

No student will be permitted to take up more than two subjects in any one year, and women will not be permitted to take more than one subject in a year.

The examination, except for mathematics, will be based on the syllabus of the several subjects given in the Science Directory; but the two stages, elementary and advanced, will be treated as a whole—one paper only being set. These examination papers will be framed much as the present May papers are framed, that is to say, with a certain number of compulsory questions and a certain number of optional questions, some of the latter being more difficult and more highly marked than the rest. Questions will also be set on the method of teaching various branches of the subject.

The successful students will be placed in the first or second class, the standard for a second class being as high as that of a *good* second class in the present advanced stage, and for the first class of a *good* first class in the advanced stage. All students who pass will be registered as qualified to earn payments on results and will receive certificates, but no prizes will be given. A payment of 3*l.* will be made on account of each first class, and 1*l.* 10*s.* on account of each second class obtained by a student in a training college.

In addition to the payments for theoretical chemistry, payments will be made for practical chemistry, of the same amounts and on the same conditions as those detailed in the Science Directory, § XLV. The circular contains an appendix with a syllabus of the subjects for mathematics in training colleges. We should advise all interested in this matter to obtain a copy of the circular.

SUN-SPOTS AND TERRESTRIAL MAGNETISM

I HAVE seen only to-day the number of NATURE (vol. xvii. p. 220) containing a letter from Prof. Piazzi Smyth on the above subject. I have also just now seen for the first time a communication from M. Faye to the French Academy of Sciences on July 30 last, in which there is a reference to the same subject: this I regret much, as M. Faye, through an incomplete acquaintance with my investigations, has drawn conclusions from one of them which are not exact. I shall at present refer only to the subject of Prof Smyth's letter.

M. Faye considers the difference of the periods found by Dr. Lamont and myself for the diurnal oscillations of the magnetic needle (10·45 years) and by Dr. Wolf from the sun-spots (11·11 years), a sufficient proof that these cycles are not synchronous, and therefore that there is no causal connection between the two phenomena. Prof. Smyth asks an explanation relatively to this difference, upon the supposition that the two periods found are the true mean durations of the cycles for the respective phenomena. This supposition, however, is erroneous, and consequently M. Faye's deductions from it fail.

I have shown in a paper cited by M. Faye[1] that if we determine the epoch of the maximum diurnal oscillation of the needle from Cassini's observations made at Paris, and from Gilpin's observations made at London, we find it to have occurred in 1787·25. This epoch agrees very nearly with that deduced by Dr. Wolf for the maximum of sun-spots. If we compare this epoch with that of the last maximum which occurred for both phenomena near the end of 1870, we shall obtain a mean duration of 10·45 years, upon the assumption that eight cycles happened between these two epochs. There is no difference between Dr. Wolf and the magneticians excepting upon the question whether there were eight or only seven cycles. Dr. Lamont considers that the data existing between 1787 and 1818 are worthless for a decision upon this point, and by induction from the known cycles has concluded that three cycles must have occurred in the thirty-one years 1787 to 1818. Dr. Wolf believes there were only two. I have given the evidence which makes the existence of three extremely probable. This question has no relation whatever to the synchronism of the two phenomena.

If we could accept Dr. Wolf's view we should find, as I have shown, that the mean duration of a cycle for *both* phenomena since 1787 would be 11·94 years, while the sun-spot results for eight cycles determined by Dr.

---

[1] "On the Decennial Period," *Edinb. Trans.*, vol xxvii.

Wolf during eighty years *before* 1787 give 10·23 years (or, if we take nine cycles, 10·43 years) for the mean duration. It is by mixing these two very different means that the Zurich astronomer finds 11·1 years, a mean that can evidently have no weight given to it. On the other hand, if Dr. Wolf is in error (as I believe he is) as to the existence of a maximum in 1797, the mean durations for the eighty years after, and for the eighty years before 1787 agree as nearly as the accuracy of the determinations for the beginning of the eighteenth century will admit.

I beg, then, to repeat that since the time when regular series of magnetic observations were commenced, till now, there is no difference whatever between Dr. Wolf and the magneticians as to the synchronism of the two phenomena.

Under these circumstances we come to the question—Are the sun-spot maxima and minima really synchronous with those of the magnetic diurnal oscillations? I have already said that this was so in 1787; and, considering only the cases for which we have complete materials for comparison, beginning with Schwabe's observations of sun-spots, it was so for the maxima of 1829, 1837, 1848, 1860, and 1870, and for the minima of 1824, 1833-4 (*q. p.*), 1844, 1856, 1866, and it is the case for the minimum at the present time. These coincidences are far more important, as showing a common cause, than may appear at first sight from this summary.

The successive oscillations of the sun-spot variations are not performed in equal times, neither are those of the magnetic variations. Was the duration of the oscillation for the sun-spots only eight years, as from the maximum in 1829 to that of 1837, so was that for the magnetic variations; did it amount to 12½ years nearly, for the sun-spots, as from the minimum of 1844 to that of 1856, this was also the case for the oscillations of the needle. Does the sun-spot variation proceed from a minimum to a maximum within about three and a half years as from 1833-4 to 1837, so does the magnetic oscillation. Does the sun-spot variation occupy nearly eight years between a maximum and the following minimum, as from 1848 to 1856, so does the diurnal oscillation of the needle.

It will be difficult to persuade physicists that, during nearly a century the sun-spot cycle has been shortened or lengthened, and the sun-spot variations have been accelerated or retarded, so nearly together with those of the diurnal oscillations of the magnet, by accidental coincidences. No doubt the admission of the existence of a causal connection between the two phenomena is opposed to the hypothesis, which many other facts render now wholly untenable, that the magnetic variations are due to the heating action of the sun.

I am obliged to Prof. Piazzi Smyth for giving me the occasion to explain a difficulty which has troubled others as well as himself. JOHN ALLAN BROUN

January 23

HENRI VICTOR REGNAULT

THE death of M. Becquerel, alluded to in our last issue, was followed on the 19th inst. by that of his friend and fellow-physicist, M. Regnault, whose name is associated so intimately with the elementary principles of our knowledge of heat. Henri Victor Regnault was born at Aix-la-Chapelle, July 21, 1810. His youth was spent in a hard battle against poverty in the effort to maintain not only himself, but his sister. While still a lad he wandered to Paris, and there obtained a position as assistant in the large drapery establishment known as Le Grand Coude, a name familiar at the present day to the lady visitors of Paris. Here ability and fidelity won for him friends, and at the age of twenty he was enabled to gratify his longings for a scientific education, and enter the École Polytechnique of Paris, the Alma Mater of so many famous French *savants*. After a course of two years here, in 1832 he entered upon active duties in the department of mines, and was absent from Paris for the next eight years. During the latter portion of this time he occupied a professor's chair at Lyons, and had a laboratory at his disposal. Here he embraced the opportunity to enter upon the field of research in organic chemistry, which had just sprung into existence as a branch of chemical science, under the hands of Liebig, Wöhler, Laurent, Dumas, and others. While many of the chemists of the day were engaged in theoretical disputes, and the battle between the electro-chemical theory and the newly-advocated type-theory was being hotly waged, Regnault devoted himself to the accumulation of the facts so sorely needed as foundation-stones by the disputants on both sides. Among his investigations at this time may be mentioned those on the composition of meconine, piperine, cantharidine, and other alkaloids, composition of pectic acid, identity of esquisetic acid with maleic acid, properties of naphthaline-sulpho-acid, &c. By the action of sulphuric anhydride on ethylene, he obtained the carbyl-sulphate, $C_2H_4S_2O_6$, which Magnus prepared later from alcohol. His most valuable researches, however, were on the halogen derivatives in the ethyl-group, especially interesting at the time of their appearance, when the theories of substitution were timidly being advocated. Among these compounds now familiar reagents to the organic chemists were mono-chloro-ethylene-chloride, $CH_2Cl.CHCl_2$, obtained by the action of chlorine on ethylene chloride, as well as the higher chlorinated derivatives, which offered one of the most striking instances of substitution. These were followed shortly after (1838) by the classical investigations on the actions of chlorine on ethyl-chloride C_2H_5Cl, in which one by one all of the hydrogen atoms were successively substituted by chlorine, until the limit, C_2Cl_6 was reached. Of importance also was the change of ether, $C_4H_{10}O$, into perchloroether, $C_4Cl_{10}O$. Another interesting series of preparations gave the substituted ethylenes by the action of alkalies on saturated halogen derivatives, ethylene-bromide for example, yielding vinyl-bromide, and hydrobromic acid:—

$$C_2H_4Br_2 + HKO = C_2H_3Br + KBr + H_2O.$$

By this method he discovered vinyl-bromide, vinyl-iodide, vinyl-chloride, dichlor-ethylene, $C_2H_2Cl_2$, and trichlor-ethylene, C_2HCl_3. Finally must be mentioned his discovery of carbon-tetrachloride, CCl_4, by leading chlorine into boiling chloroform. It is difficult for us at the present day to estimate the importance attached to these discoveries forty years ago, when every new fact was a glimmer of light to the organic chemist wandering in the dark, and few series of researches have stood the test of time so well as those carried out by Regnault in his Lyons laboratory. The faithful study of minute properties, and the careful attention to physical peculiarities, already gave evidence of the tendencies which were manifested more fully in another branch of science, and the appearance of his papers in the *Annales de Chimie et Physique* attracted the attention of the scientific world to the hitherto unknown provincial professor. In 1840 he was elected to replace Robiquet in the chemical section of the French Academy, and was appointed professor in the École Polytechnique. In the following year he was elected to the chair of physics at the Collège de France. A few years later he became engineer-in-chief of mines, and in 1850 received the order of officer in the Legion of Honour.

With his removal to Paris the field of Regnault's investigations was changed. Like our own Faraday, after having obtained renown as a chemist, he suddenly turned physicist. He was scarcely established in Paris, when he began his famous series of experiments on specific heat. A few years previous, Dulong and Petit had determined the specific heat of a number of elements by means of their calorimeter based on the method of cooling, and obtained data sufficiently accurate to warrant the establishment of their law that the product of the specific heat of an element and its atomic weight is a constant. Regnault, after having submitted their method to careful examination, found it useless for the exact determination of the specific heat of solids, and invented in its place the calorimeter bearing his name. It is based on the method of mixtures, viz., of heating a known weight of a substance to a known temperature, immersing it in a known weight of water at a known temperature, and determining the temperature of the mixture. With this apparatus, which is of a somewhat complicated character, in order to reduce to a minimum the possibilities of error, Regnault determined the specific heat of the liquid and solid elements, and of a great variety of compounds. From the comparison of these results he deduced the general law that for all compounds of the same formula and similar chemical constitution the product of the specific heat and the atomic weight is the same. He also confirmed, by his experiments, the hypothesis of Wostyn, that the elements require the same amount of heat to be raised to a certain temperature, whether free or in combination, and showed, by his more exact results, the general truth of Dulong and Petit's law. In order to overcome the difficulties of determining the specific heat of gases, Regnault contrived an ingenious apparatus in which the gases passed through a spiral inclosed in a known weight of water. The volume of gas, its temperature on entering and leaving the apparatus, and the alteration in the temperature of the water supplied the necessary data. By this means he experimented with about thirty-five of the principal gases and vapours, and established the two important laws, 1, that the specific heat of any gas at constant pressure, whether simple or compound, is the same at all pressures and temperatures; and 2, that the specific heats of different simple gases are in the inverse ratio of their relative densities. Regnault prepared also an interesting table of the specific heats of various substances in the solid, liquid, and gaseous forms, from which it appears that the specific heat of the same body is commonly greater in the liquid than in the solid state, and always greater than in the gaseous state.

In his experiments upon heat Regnault was led to devise methods of measuring high temperatures accurately, and invented the well-known air thermometer, which can be used at all temperatures below that at which gas softens, and the mercury and hydrogen pyrometers, the latter of which permits the determination of the temperature in a furnace at any instant. In this connection he carried out also an elaborate series of experiments on the density and absolute expansion of mercury from 1° to 360°, the results of which, as tabulated, are of primary importance in the correction of thermometers and barometers, as well as in a multitude of physical experiments conducted with this liquid. Still more elaborate and exhaustive are the extensive series of determinations in connection with water, its specific heat at various temperatures, the tension of its vapour at various temperatures, and the latent heat of its vapour at various pressures, all of which were designed to serve as fundamental facts upon which to base the action of heat on water for industrial purposes. The specific heat of water was found to increase from 1 at 0° to 1·013 at 100° and 1·056 at 230°. For the determination of the tension of steam Regnault contrived a simple apparatus based on the fact that the maximum tension of steam at the boiling-point is equal to the external pressure, by the aid of which he was able to construct his table of tensions from 0·32 mill. at 32° to 20926 mill. at 230°.

The experiments with this apparatus were extended to a number of volatile liquids with the design of testing the truth of Dalton's supposition that the tension of the vapours of all liquids is the same at temperatures equally distant from their boiling points, and the results showed that although not a law, it was very nearly correct for small intervals of temperature in the neighbourhood of the boiling point. A variety of interesting results were also obtained from mixtures of gases and vapours, including the laws that a liquid does not give off a vapour of so high a tension in the presence of a permanent gas as in a vacuum, and that while the tension of the vapours of a mixture of liquids not dissolving each other is equal to the sum of the tensions of its liquids at the same temperature; on the contrary, the tension arising from a mixture of mutually solvent liquids is less than the sum of the individual tensions.

Perhaps the most important of Regnault's experimental investigations was that on the coefficient of expansion for air and other gases, as well as on the compressibility of gases. Dalton, Gay-Lussac, and Rudberg had obtained numbers for the coefficient of expansions differing widely from one another. It was reserved for Regnault to establish by the most delicate experiments the number ·03663 as the coefficient of expansion of air, and to show in addition that the law of Dalton and Gay-Lussac with regard to the regularity of expansion among gases was only approximately correct. A similar result was obtained in his investigations on the accuracy of Boyle and Mariotte's Law, on the compressibility of gases.

In addition to the chief lines of research alluded to, Regnault made a variety of interesting experiments on the phenomena produced by heat, and his hypsometer and hygrometer should be mentioned, on account of their simple and practical qualities. Some valuable investigations on the phenomena of respiration were made by him in connection with Reiset, and, together with Dumas, he carried out a lengthy research on illuminating gas.

His most valuable experimental results are collected together in vol. xxi. of the *Mémoires* of the French Academy, and a continuation is to be found in vol. xxvi. Regnault published, in 1847, a treatise on chemistry, which has survived numerous editions in France, and been translated into German, English, Dutch, and Italian.

In 1854 he was appointed director of the famous porcelain manufactory of Sèvres, and since that date much of his time has been devoted to improvements in ceramic processes. During the Franco-Prussian war he received a sad blow in the death, on the battle-field, of his second son, Henri Regnault, a promising artist, and universal favourite in Paris. He returned to his laboratory at Sèvres, after the declaration of peace, to find that the results of his last great research on the phenomena of heat accompanying the expansion of gases, derived from over 600 observations, had been destroyed. The announcement of this loss was his last communication to the scientific world. Since then, oppressed by grief and a victim to increasing infirmities, he has been forced to renounce his wonted pursuits. On the day when the gay artist world of Paris was celebrating the battle of Buzenval by laying wreaths on the grave of the young patriot-painter, the father was released from a long and painful illness by the hand of death.

As a scientific investigator, Regnault did not possess the brilliant originality of many of his fellow-physicists. It is as the patient, thorough, conscientious observer that he has won his way to the foremost rank. Possessing a wonderful ingenuity in the invention of mechanical appliances for the purposes of observation and a perfect familiarity with the mathematical department of physics, he has been enabled by means of his unflagging enthusiasm and unbending resolution to place the modern physicist and chemist in possession of an invaluable collection of constants, which at the present stage of science are in daily use not only in the laboratory of research, but fo[illegible] large variety of industrial purposes.

T. H. N.

THE ORIGIN OF A LIMESTONE ROCK[1]

IN November, 1845, I laid before the Literary and Philosophical Society of Manchester my memoir "On some Microscopic Objects found in the Mud of the Levant and other Deposits; with Remarks on the Mode of Formation of Calcareous and Infusorial Siliceous Rocks," which memoir was published in vol. viii. of the second series of the Society's *Transactions*. In that memoir I sought to demonstrate two things—1st, that not only was Chalk made up of microscopic organisms, chiefly Foraminifera, as had recently been demonstrated by Ehrenberg, but that the fact was equally true and explanatory of the origin of all limestones except a few freshwater Travertins; 2nd, that some other extensive deposits, of submarine origin, in which no Foraminifera could now be detected, were not in the state in which they were originally accumulated. I concluded that Foraminifera had doubtless been present in them also, but that their calcareous shells had been dissolved out of them, and that this disappearance had been effected through the agency of water containing carbonic acid, at an early stage of the formation of these deposits. As is well known, this latter theory has been reproduced as a new one by some of the naturalists of the *Challenger* expedition, who have applied it to the explanation of phenomena of a substantially similar nature to those which I endeavoured to account for, in the same way, more than thirty years previously.

I am indebted for the slab of limestone forming the subject of this communication to my friends the Messrs. Patteson, the marble merchants of Oxford Street, Manchester. This slab appears to illustrate in an exquisite manner both the theories to which I have just referred. It is a specimen of the Bolland limestone, which, when sawn through, was found to contain a large concamerated Nautiloid shell more than twelve inches in diameter, which appears to me to have been a true Nautilus, though the section has not passed exactly through its centre so as to reveal any portion of its siphuncle. In the various parts of this slab we find the calcareous material exhibiting different conditions. Throughout the greater part of its substance we have evidence that it has originated in an accumulation of minute calcareous organisms—especially Foraminifera—but most of these are disintegrated and display vague outlines, a condition which I presume has resulted from the action of the carbonic acid already alluded to.

Scattered through the slab are numerous dark-coloured patches of a substance apparently identical with what the late Dr. Mantell designated Molluskite, and which he believed to be the remains of the soft animal substance of marine organisms. In many of these patches the Foraminiferous shells are better preserved than is the case with the rest of the matrix inclosing the large fossil shell. It appears as if this Molluskite had partially protected the calcareous Foraminifera from the solvent action which had disintegrated most of those forming the rest of the deposit.

But the most interesting features of the specimen are seen within the chambers of the Nautiloid shell. The Foraminiferous ooze has entered freely through the large, open mouth of the terminal chamber in which the animal resided and filled the entire cavity of that chamber. There is no doubt whatever as to the original identity in the character of the ooze thus inclosed within the shell and that which constitutes its investing matrix, though they now appear very different. The latter portion was freely permeated by water containing the solvent carbonic acid; hence the more or less complete disintegration of its Foraminiferous shells. But in the limestone inclosed within the large terminal chamber of the Nautiloid shell almost every Foraminifer is preserved in the most exquisite perfection. This is especially the case in the deeper part of the chamber, most remote from the mouth, as also in the instances of one or two of the more internal closed chambers, into which the mud has obtained entrance through small accidental fractures in the outer shellwall. It appears obvious to me that the thick calcareous shell of the Nautilus has protected the inclosed shells of the Foraminifera from the action of the solvent acid. I repeat that there is no room whatever for doubting that both portions of the Foraminiferous ooze, whether contained within or surrounding the Nautiloid shell, were originally in identical states. Microscopic observation makes this sufficiently plain. The differences now observable between them have arisen from changes which have taken place subsequent to their primary accumulation, and which changes have been due to differences of position; the one portion has been protected by the thick calcareous Nautiloid shell which would rob the water percolating through it of all its solvent carbonic acid, and thus preserve the contained Protozoa from destruction, and which protection would continue so long as any portion of the Nautiloid shellwall remained undissolved. The other, being unprotected, would be exposed to the full action of the solvent, which would percolate readily amongst the loosely aggregated microscopic organisms, and speedily act upon their fragile shells.

But there is a yet further feature in this interesting specimen requiring notice. The *closed* chambers of the Nautiloid shell are all filled with clear, crystalline, calcareous spar. The acidulated water, acting upon the calcareous Foraminifera of the ooze has become converted into a more or less saturated solution of carbonate of lime. This has passed, by percolation, through the shell of the Nautilus into its hollow chambers. Finding there suitable cavities it has gradually filled them up with a crystalline formation of calcareous spar, and which of course exhibits no traces of the minute organisms from which the calcareous matter was primarily derived. A similar crystallisation has filled up the smaller interspaces between the Foraminiferous atoms both inclosed within, and external to, the Nautilus, rendering the limestone capable of receiving a high polish.

If these explanations are as correct as I believe them to be, we have here the entire history of the origin of a limestone rock—from the first accumulation of the Foraminiferous ooze, as seen in the interior of the first large chamber of the Nautilus, to the deposition, in an inorganic mineral form, of the crystallised carbonate of lime within the closed chambers of the Nautilus, all being illustrated within the area of a slab of limestone little more than a foot in diameter.

---

THE LIQUEFACTION OF THE GASES

IN the recent article, in which the magnificent results recently obtained by MM. Cailletet and Pictet were detailed, we contented ourselves, in the account of the methods employed, by pointing out the extreme simplicity of that used by M. Cailletet. The simplicity, however, by no means takes away from the beauty of the method, and we now propose to return to it with a view of showing how closely it resembles in many of its details that employed by Dr. Andrews in his classical work on the continuity of the various states of matter.

Dr. Andrews, it will be remembered, in his experiments on the liquefaction of carbonic acid, used a glass tube capillary in the upper part, and in the remainder, of a bore just so wide that a column of mercury would remain in it when the tube was held in a vertical position. The gas to be operated on was confined to the narrow upper part of the tube by mercury, and the tube was tightly packed to an end piece of brass armed with a flange.

This permitted a water-tight junction with a corresponding end of a cold-drawn tube of copper of great strength. A similar end-piece was attached to the other extremity of this

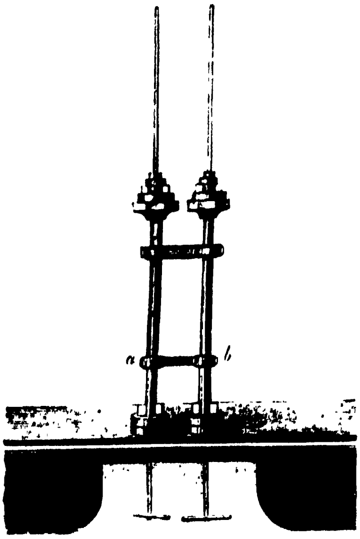

Fig. 1.—Two of Dr Andrews's tubes on a stand as in use

copper cylinder, and in the centre was a fine screw most carefully made and fitted, seven inches long, and packed so as to resist a pressure of 400 atmospheres or more.

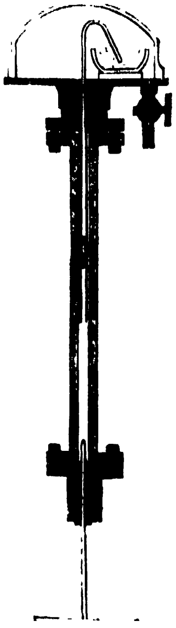

Fig. 2.—Section of Tube. Fig. 3.—Arrangements for Utilising Low Temperatures.

When low temperatures as well as high pressures were required, the tube was bent, as shown in Fig. 3, and inserted in a freezing mixture.

In all these tubes the pressure is produced by screwing up the mercury into the capillary tube.

We have next to consider the phenomena which Dr. Andrews observed, taking carbonic acid as an example.

On partially liquefying the gas by pressure and changing the temperature, the surface of demarcation between the liquid and the gas became less and less distinguishable, the tube seemed to be filled with a homogeneous fluid which, when the pressure was suddenly diminished, or the temperature slightly lowered, broke up into striæ, Fig. 4.

A cloud was also formed if the temperature were allowed to fall a little below the "critical point" $30^\circ{\cdot}92$ C., showing the formation of liquid particles, Fig. 5.

We may now pass to M. Cailletet's method and the phenomena he observes, Fig. 6, for which we are indebted to the courtesy of the editor of *La Nature*, represents the great apparatus which M. Cailletet has constructed at his works of Châtillon-sur-Seine.

The apparatus is composed of a hollow steel cylinder A solidly fixed to a cast-iron frame by means of the hoops B B. A cylindrical shaft of soft steel acting the part of a plunger enters this cylinder, which is filled with water. The opposite extremity of the shaft is terminated by a square-threaded screw, which traverses the bronze nut F, fixed in the centre of the fly-wheel M. According to the direction given to the fly-wheel by means of the handles with which it is provided, the plunger may be advanced into or withdrawn from the axis of the body of the pump. A leather packing prevents the compressed liquid from escaping from the cylinder.

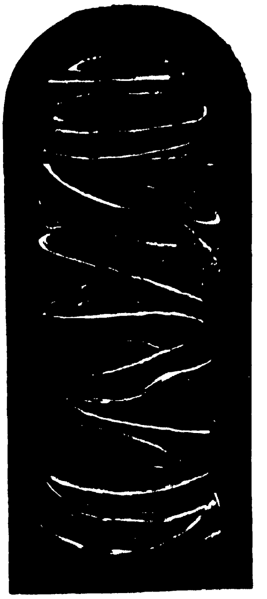

Fig. 4.—Striæ.

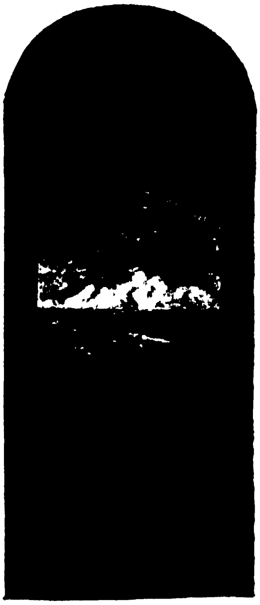

Fig. 5.—Cloud.

In order to introduce the water or the liquid to be compressed, it is poured into the glass vessel G, which is in communication with the interior of the apparatus; a steel screw with conical point closes the narrow pipe through which the liquid passes. This screw is terminated by a small fly-wheel O, with handles. This arrangement permits of suddenly expanding the compressed gases, and seeing the cloud produced in the capillary tube where the gas under experiment is contained. (This tube is represented in the centre of the glass envelope, *m*.) The cloud is formed under the influence of the external cold produced by the sudden expansion, a certain sign of the liquefaction or even of the solidification of the gases regarded hitherto as permanent. *a* is a hollow steel reservoir

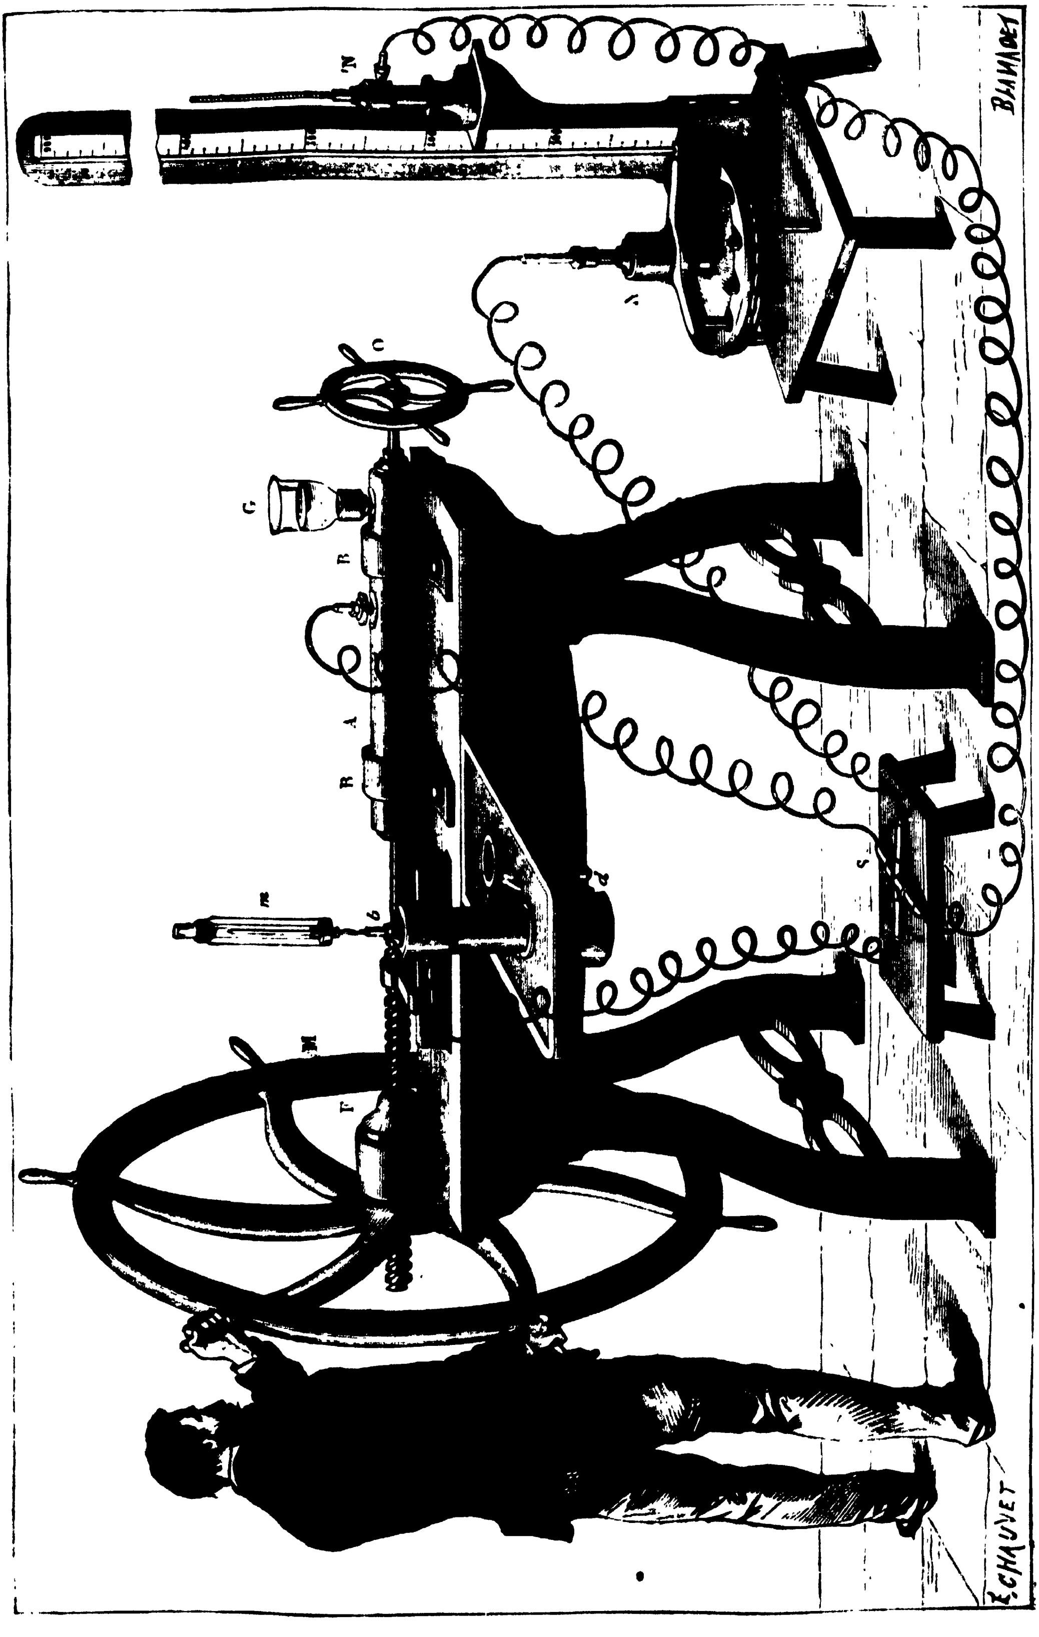

FIG. 6.—Great apparatus of M. Cailletet for the liquefaction of the gases. A, screw-press for compression; *m*, glass cylinder, containing the glass tube in which the gas is liquefied.

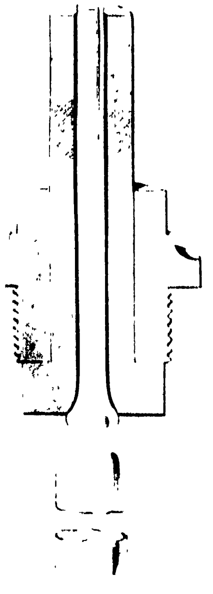
capable of supporting a pressure of from 900 to 1,000 atmospheres; it is connected with the compression apparatus by a capillary metallic tube. The water, under the action of the piston, arrives in this reservoir, *a*, and acts upon the mercury which compresses the gas. *b* represents the tube which connects this with the glass intended to contain the gas under experiment. A nut serves to fix this piece to the upper part of the reservoir. Fig. 7 shows this arrangement in half-size.

m is a glass cover containing a cylinder of the same material, in the middle of which is a small tube in which the liquefaction of the gas takes place. This capillary tube may be surrounded with refrigerating mixtures or with liquid protoxide of nitrogen. The exterior cover, *m*, concentric with the first, and containing substances strongly absorbent of moisture, prevents the deposit of ice or vapour on the cooled tube in which the experiments are made. *p* is a cast-iron tablet intended to support the reservoir, *a*; the screws, *d d*, enable the reservoir to be raised or lowered for the spectroscopic examination or the projection of the experiments. An arrangement, S, unites the capillary metallic tubes which transmit the pressure to the various parts of the apparatus. N is a modified Thomasset manometer verified by means of an air manometer established on the side of a hill near the laboratory of Châtillon-sur-Seine. N′ represents a glass manometer which serves to control the indications of the mercury apparatus.

It is a fortunate thing that the students of science in France have not been forgotten by M. Cailletet. He has not only devised the instrument above described for his own work, but he has occupied himself with a small lecture or laboratory apparatus which M. Ducretet has constructed according to his directions. It is an exact copy of the part, *a*, *b*, *m* of the apparatus of Châtillon-sur-Seine. The bell-glass alone is modified. The screw-press is, moreover, replaced by an easily-worked pump. In Fig. 8 T′ T is a glass tube filled with the gas to be compressed; the tube has been traversed by the gas until air has been entirely excluded; for this purpose it is placed in a horizontal position. When it is filled with the gas to be experimented on it is hermetically sealed at its extremity, *p*, closed with the finger at the other end, and introduced vertically into the iron apparatus as represented in the figure. It is inserted into a cylindrical cistern containing mercury. The upper part of the tube is enveloped in a glass envelope, M, filled with a refrigerating mixture. The whole is enveloped in a glass jar, G. The tube, T U is connected with a compressing pump, which is worked with the hand. The water compressed by the pump acts on the upper part of the mercury indicated in the figure by horizontal lines. This mercury is driven back into the



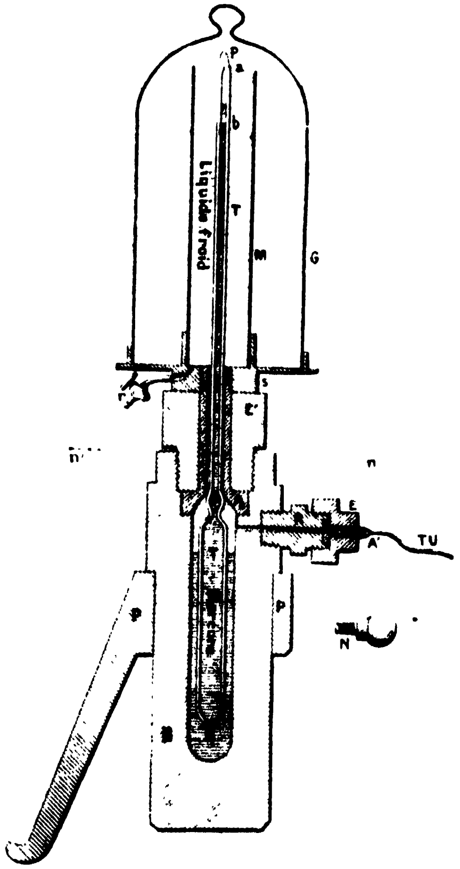


FIG. 8

FIG. 7.—Glass tube with thick sides in which the liquefaction of the gas is effected in M. Cailletet's apparatus. The gas is compressed in the upper part of the tube by the ascent of a column of mercury placed in connection with a screw-press acting on a mass of water. It condenses in a liquid drop or into mist under the action of expansion. This glass tube is enveloped in an envelope of the same substance containing the refrigerating mixture. See the centre of the tube *a* in Fig. [illegible] FIG. 8.—Small apparatus for the liquefaction of gases.

tube T T; it reduces the space *a b* occupied by the gas, and is soon surmounted by droplets of the compressed gas, which unite into a little mass of liquid, *h*.

The following are the parts of the apparatus:—E, a block of malleable iron with strongly-resisting walls; E′, E, screw nuts which may be unscrewed to arrange the apparatus before using it; P P, very solid tripod which receives the apparatus; S, support of the bell G and the envelope M; N supplementary screw intended to close the hole in the joint K when the mercury is poured into the apparatus.

OUR ASTRONOMICAL COLUMN

THE ROYAL OBSERVATORY, CAPE OF GOOD HOPE.—Since the appointment of Mr. Stone to the directorship of this establishment, in 1870, not only have all arrears of observations with the transit-circle, first brought into use in 1855, been reduced and published, but Mr. Stone has lately issued the results of observations taken in 1875, and has thereby overtaken the position of publications of the Royal Observatory, Greenwich, and the Radcliffe Observatory, Oxford, which have been conspicuous amongst astronomical establishments for the expedition with which the great mass of work involved in the reduction of the observations has been performed, and the results given to the scientific public.

The chief work of the year was the continuation of the general re-observation of the stars in the *Cœlum Australe Stelliferum* of Lacaille, attention in 1875 having been directed to those stars lying between 145 and 155° of north polar distance at the present epoch, all of which appear to have been observed, usually three times in both elements, together with a number of other stars in the same zone, which, though not generally much below the seventh magnitude, were not observed by Lacaille. Mr. Stone mentions that stars within limits of N.P.D 135°–145° were observed in 1876, and stars between 125°–135° in 1877.

Should it be deemed advisable shortly to form another general catalogue of stars, similar to the British Association Catalogue, say to stars of the seventh magnitude inclusive, Mr. Stone's recent volumes will be of the utmost value in extending the precision now attainable for such stars in the northern hemisphere to the southern heavens, not only as regards positions for the present epoch, but in the determination of proper motions of a considerable number of stars by comparison with Taylor's catalogues, which have not yet been systematically examined for that purpose. And we will take this opportunity of expressing the hope that if another catalogue like the B.A.C. should be undertaken, the time, labour, and expense involved in the preparation of so-called star-constants may be avoided, and attention paid instead to a more general and systematic investigation of proper motions, which, it can hardly be doubted, must lead to results of great interest and importance.

THE TOTAL SOLAR ECLIPSE OF JULY 29.—It was mentioned in NATURE last week that facilities would be afforded to intending observers of this phenomenon near Denver, Colorado, one of the chief places included in the belt of totality in the United States, and situated on the Pacific line of railway. By the elements of the *Nautical Almanac* the track of central eclipse appears to pass about twenty-five miles south of Denver, assuming its longitude from Greenwich to be 7h. 0m. 20s. W., and latitude 39° 48′, and at Denver the total phase commences at 3h. 28m. 14s. local mean time, and continues 2m. 45s., with the sun at an altitude of 42°; the circumstances by the elements of the American ephemeris are almost identical, as indeed was to be expected seeing that the moon's lace in the latter work differs from her place in the *autical Almanac* by only + 3″·4 in R.A. and + 1″·0 in l. and the sun's place by − 1″·1 in R.A. and + 0″·3 in decl., while the semi-diameters employed are each less by about 2″. In the American ephemeris the lunar tables of Peirce and the solar tables of Hansen are employed.

The northern and southern limits of totality in the eclipse of July 29, with the duration of total phase upon the central line, for nearly the whole track across the North American continent will be found at p. 400 of the *Nautical Almanac* for 1878.

CHEMICAL NOTES

TEMPERATURE OF FLAMES.—In the *Gazetta chimica Italiana* an account is given by F. Rosetti of some experiments on the above subject. To examine the temperatures he employs a thermo-electric element consisting of an iron and a platinum wire wound closely together and connected with a galvanometer. This latter was graduated to various temperatures by observing the deviation consequent on bringing the element in contact with a copper cylinder heated to known temperatures; these being determined by introducing the cylinder into a calorimeter. With such an arrangement he has investigated the flame of a Bunsen's burner, finding that in the same horizontal strata there were but slight alterations in the temperature, with the exception of the dark interior portion. Thus, where the external envelope showed 1,350°, the violet portion of the flame was 1,250°, the blue 1,200°, but the internal portion much lower, its temperature gradually decreasing from the base of the flame upwards. A flame produced by the combustion of a mixture of two volumes of illuminating gas and three volumes of carbonic oxide, showed a temperature of 1,000°

STARCH IN PLANTS.—Botanists have hitherto held that all the starch in the chlorophyll cells of the leaves of plants is a product of the direct assimilation of carbon dioxide and water, basing this belief on the fact that the starch in these cells disappears when the plants are deprived of the power of assimilating carbon dioxide, but reappears on their exposure to light in an atmosphere containing that substance. Prof. Bohn, of Vienna, in a recent number of the *Deut. chem. Ber.*; throws some doubt on this conclusion by experiments he has made on the leaves of the scarlet runner. His results show that if the primordial leaves of this plant are shaded from light, the starch at first entirely disappears; after a few weeks, however, the chlorophyll cells of these shaded leaves show almost as high a percentage of starch as the parts of the plant which have been exposed to light. These observations demonstrate, therefore, that starch can be formed in the leaves from matter which has already been assimilated, and has entered into the leaf after its removal from the sunlight.

SIPYLITE, A NEW MINERAL CONTAINING NIOBIUM.—Mr. Mallett has found this mineral among some quantities of allanite from Amhurst county, Virginia. A few crystals have been obtained, but as they are of rather imperfect nature the measurement of the angles has only been attempted in a rough manner. The mineral in the mass was of a brownish black nature, but in thin plates it exhibited a reddish-brown colour, and possesses a pseudo-metallic lustre. The hardness is estimated at about 6, and the specific gravity as equal to 4·89. From the results of analyses Mr. Mallet considers that placing together the acid oxides of niobium, tantalum, tungsten, tin, and zirconium, reducing the basic oxides to equivalent amounts of dyad oxides, and eliminating the water, the following ratio may be obtained:—$R''O : M^{v}_2O_5 = 221 : 100$, leading to the formula $R''_3M^{v}_2O_8 \cdot 4R''_2M^{v}_2O_7$, that is a single group of orthoniobate associated with four of pyroniobate. If the water be taken into account in the calculation and considered basic, then placing it on the same footing as the dyad oxides, we should have the relation $R''O : M^{v}_{2}O_{5} = 311 : 100$, or nearly 3 : 1, thus giving the simple formula $R''_{3}M^{v}_{2}O_{8}$; this latter the author considers the more probable. Whatever formula, however, may be taken for the mineral it differs from niobates hitherto described, the one view making it an approach to a simple pyroniobate, the other making it an orthosalt like Fergusonite, but partially acid in character, or containing basic hydrogen.

MOLYBDENUM.—The atomic weight of this metal has hitherto been quite uncertain, some chemists regarding it as 96, others as 92. Fresenius, the leading authority in analytical chemistry, has always adopted the latter number. Prof. Rammelsberg, of Berlin, has lately settled the question by careful experiments on the reduction of molybdic acid in an atmosphere of hydrogen, and has found 96 to be the correct atomic weight, – 96·18 being the exact number obtained. Taking this number as a basis, he has sought to solve the problem of the composition of the yellow phospho-molybdate of ammonium, which is used generally for the determination of phosphoric acid, and the exact formula of which has never been satisfactorily determined. A large number of analyses of the ammonium salt and the corresponding potassium salt show that the composition is undoubtedly

$$3(NH_4)_2O + P_2O_5 + 22MoO_3 + 12H_2O.$$

RELATIONS BETWEEN THE VOLUMES OF SILVER SALTS.—H. Schröder communicates an interesting series of observations on this subject in the *Berichte der deutschen chemischen Gesellschaft*, for November, from which it appears that the atomic volumes (*i.e.*, the quotient resulting from the division of the molecular weight by the specific gravity) of these salts are all simple multiples of the atomic volume of silver, or rather of its half atomic volume, 5·14. In the fatty series an accession of CH_2 to a compound increases the atomic volume by 3 × 5·14. For example :—

$$C_2H_3AgO_2 = 10 \times 5{\cdot}14 = 51{\cdot}4$$
$$C_3H_5AgO_2 = 13 \times 5{\cdot}14 = 66{\cdot}8$$
$$C_4H_7AgO_2 = 16 \times 5{\cdot}14 = 82{\cdot}2$$
$$C_5H_9AgO_2 = 19 \times 5{\cdot}14 = 97{\cdot}7, \text{ \&c.}$$
$$C_6H_5CAgO_2 = 20 \times 5{\cdot}14 = 102{\cdot}8$$
$$C_4H_4Ag_2O_4 = 17 \times 5{\cdot}14 = 87{\cdot}4.$$

ORNITHURIC ACID.—Prof. Jaffe, of Königsberg, in the course of experiments on the transformation of organic bodies on passing through the digestive organs of fowls, has obtained a new acid in a way decidedly different from the usual methods of chemical synthesis. Benzoic acid, C_6H_5COOH, which has been given to birds, is found to be entirely changed by passing through their organisms into a new and well-defined acid, which crystallises in colourless needles, forms a series of salts, and receives the name ornithuric acid. It appears to arise from the combination of benzoic acid with a base $C_5H_{12}N_2O_2$, present in the system, and which can be separated from ornithuric acid by treatment with hydrochloric acid. The formation is as follows :—

$$2C_6H_5COOH + C_5H_{12}N_2O_2 = C_{19}H_{20}N_2O_4 + 2H_2O.$$

DISTILLATION OF ORGANIC LIQUIDS BY MEANS OF STEAM.—Prof. Naumann, of Giessen, describes, in a recent series of papers in the *Berichte der deut. chem. Gesellschaft*, the results of his observations on the phenomena attendant on the passage of steam through organic liquids. As is well known to the experimental chemist, aqueous vapours, on passing through a liquid, carry with them frequently large portions of the latter, even when it boils at a temperature far above that of water—aniline, for example, at 180°. The process also is one of every-day occurrence in the organic laboratory, being used for the purpose of separating such liquids from their impurities. Prof. Naumann has studied in this connection liquids both specifically lighter and heavier than water, as well as liquids boiling below and boiling above 100° C., recording the physical phenomena produced by the passage through each of a regular current of steam. In all cases he finds them obeying a few invariable laws, viz., 1°. For every mixture of a liquid with water there is a constant boiling-point, which is below that of the lower boiling liquid ·2°. A constant ratio exists between the respective quantities of the two liquids found in the distillate ·3°. The temperature of the distilling vapours is always slightly higher than that of the mass of liquid. From among the numerous results the following will convey a general idea of the experiments. The first column contains the boiling points of the respective liquids, the second the temperature of the liquid while steam is being passed through it, and the last the number of cubic centimetres of the liquid found in the distillate for every 100 c.c. of water :—

	°	°	
Benzene	79·5	68·5	8·5
Toluene	108·5	82·4	21·2
Xylene	135·5	89	44
Nitrobenzene	205	98·5	14

An attempt was made to discover a connection between the molecular weights of the three first hydrocarbons of the aromatic series and the respective quantities of these liquids in the distillates, but without success. While studying the relations of the numbers yielded by the experiments, Prof. Naumann finally discovered that all the liquids obeyed a general fixed law, viz., *when a liquid is distilled by means of steam, the ratio between the volumes of the liquids and the water in the distillate, expressed in multiples of their molecular weights, is equal to the ratio between their vapour-tensions at the temperature at which the distillation occurs.* It is at once evident that by the discovery of this law the chemist is placed in command of a most valuable auxiliary for determining the constitution of a variety of compounds at present to a certain extent doubtful. The law holds equally good for any liquid the vapour of which is used instead of that of water.

GEOGRAPHICAL NOTES

EARLY AFRICAN EXPLORER.—Don Marcos Ximenez de la Espada of Madrid is now having printed a document of extraordinary interest for geographical science, viz., an account of the travels of an unknown missionary, of the fourteenth century, which Don Marcos has recently discovered. The enterprising author, in the years from 1320 to 1330, undertook extensive travels in Africa, not only along the west coast to Sierra Leone and thence to Dahomey, but also, it is stated, from the mouth of the Senegal river straight across the interior of the great continent. He visited the Soudan States, got as far as Dongola, and thence proceeded down the River Nile, finally reaching Damietta.

AFRICAN EXPLORATION.—In reply to a question from Mr. H. Samuelson last Friday in the House of Commons, the Chancellor of the Exchequer stated that it was not the intention of Government at present to devote any public money to African exploration. We can hardly expect that they would in the present state of public affairs; and even if they could it would be difficult to see in what direction they could take action. There are many expeditions of various kinds in the African field at present, working away with little or no connection with each other; even the International African Association has not been able to organise them, but is simply sending out more expeditions. There seems to us to be considerable waste of power and resources here.

MR. STANLEY.—The Geographical Society's dinner to Mr. Stanley is to take place on February 9. Arrangements are being made to accommodate the Fellows and their friends in St. James's Hall, but as the hall holds only 2,000, and as there are between 3,000 and 4,000 Fellows, we suspect, making all allowances, that many hundreds will be disappointed. Why does the Society not boldly take the Albert Hall and admit the outside public at a moderate charge? We are sure there would be a balance over after clearing expenses.

BERLIN GEOGRAPHICAL SOCIETY.—The Berlin Gesellschaft für Erdkunde celebrates on April 27 and 28 the completion of its fiftieth year. The festival committee, consisting of Baron v. Richthofen, Dr. Nachtigal, Dr. Jagor, and other well-known explorers, have issued invitations to all the geographical societies of Germany and Austria to send delegates. It is expected that over a thousand will be present at the closing dinner. This society, founded by Alexander von Humboldt and Karl Ritter, has manifested from its commencement a vitality and energy second to none of the European geographical societies, and forms in Berlin a favourite gathering place for the leading minds in all departments of science. Its membership numbers at present 700.

AUSTRALIA.—An exploring party sent into the interior from Port Darwin, North Australia, under the leadership of Mr. Sergison, has returned to the latter place, and reports that in the vicinity of Victoria River, which runs into the Queen's Channel on the west coast of the Northern Territory, as well as near Fitzmaurice River, which flows more to the north, and near Daly River, which runs into Anson Bay, it discovered land with excellent soil, with a comparatively cool climate, and with numerous creeks in every direction.

ARCTIC EXPLORATION.—The preparations for the Dutch North Polar Expedition are being actively continued, as the expedition is to sail in May next. The first and principal halt will be made at Spitzbergen. The erection and fitting up of a station for meteorolo observations is reserved for a future expedition; the present one, however, is to select the place best adapted for a station of this nature. 10,000 florins are still wanting to cover the expenses of the expedition.

CANADA.—On December 22 last a Canadian Geographical Society was founded at Quebec. The principal aim of the society will be to obtain a thorough knowledge of the geography of Canada.

NOTES

THE distribution of the prizes for 1877 by the French Academy of Sciences took place on January 28 under the presidency of M. Peligot. For the two great prizes in mathematics and physical science no memoir worthy of mention has been sent to the academy. The subjects were very limited in their scope and it is said that the academy proposes to alter its system and confine itself to giving its highest prizes to independent workers irrespective of the subject-matter of their work. Among other prizes awarded we at present mention the following:—The Plumet prize was taken by M. de Freminville, for his improvements in marine steam engines; the Fourneyran prize was awarded to M. Malet, for tramway steam-engines, as used from Bayonne to Biarritz; the Lalande prize in astronomy has been rightly awarded to Prof. aph Hall, the discoverer of the satellites of Mars; the Valz e to the Brothers Henry, for their celestial maps; the ontyon prize in physiology was awarded conjointly to Prof. ier and MM. Carville and Duret; the Lacaize prize for the work in physics has been given to M. Cornu, the well-known sor of the Polytechnic School for his determination of the ity of light by direct measurement; the Breant prize (4,000*l*.) to the discoverer of a cure for cholera has not, of been awarded, but the interest of that sum has been given to M. Rendu, for several memoirs of etiology. A copy of Laplace's works, magnificently bound, has been delivered, as usual, in the name of Laplace's deceased wife, to the pupil of the Polytechnic School who has passed the most successful examination. The young laureate for 1877 is M. Dougadot, a native of Carcassonne (Aude), where he was born in 1855.

ON January 11 the centennial of Linné's death was observed in nearly all the cities of Sweden. In Stockholm the Academy of Sciences held a special session, attended by King Oscar, at which Prof. Malmsten delivered an interesting oration on the scientific achievements of the great botanist. At Upsala the occasion summoned together a number of notabilities who listened to an address from the Swedish botanist, Prof. Th. Fries. The university of Lund celebrated the day in a similar manner, the rector issuing, in connection with it, a short sketch of Linné's residence there, and Prof. Ogardh delivering the oration. At Frankfort-on-the-Main the memorable day was celebrated by a solemn meeting of the "Freie Deutsche Hochstift," in the Goethe House. The president, Prof. Volger, in a brilliant speech, gave an outline of the life, the mental development, the activity, and importance of Linné, and closed by praising the mental ties which unite all races and nations. The meeting unanimously resolved to send a congratulatory telegram to King Oscar II., of Sweden, which was then sent off, written in the Latin language. An hour later his Majesty telegraphed his thanks in the same language. At Amsterdam, where the great Swedish botanist passed the early part of his life, there was also a Linné celebration on Jan. 10. At the same time an exhibition of objects relating to him, such as manuscripts, medals, portraits, &c., was arranged. Prof. Oudemans delivered the memorial speech.

THE French Scientific Association has issued the programme of its weekly lectures for the next three months, and provides a most promising list of famous names and attractive subjects. Among them we notice Prof. Dumas, "Eulogy on Leverrier;" M. Wolf, "Variability of the Nebulæ," which were given on January 26; M. Cornu, "The Phylloxera," February 2; M. Jamin, "Electric Illumination," February 9; Prof. St. Claire Deville, "Liquefaction of Gases," February 23; Prof. Bert, "Influence of Light on Life," March 9; Prof. Mascart, "Atmospheric Electricity," March 23; M. Tissandier, "The Upper Regions of the Air," March 30; M. Blanchard, "Geographical Distribution of Animals," April 13. The lectures take place at the Sorbonne, and as admission is easily obtained by strangers, they offer visitors to Paris an admirable opportunity of hearing the leading French *savants*. The first meeting, on January 26, was attended by more than 1,000 people, under the presidency of M. Dumas. The proceedings were opened by a report read by M. Milne-Edwards, the president of the Association, reviewing the work done by the Association, which was created by M. Leverrier more than fifteen years ago. It is owing to the assistance lent by the Association that weather-warnings have been so largely popularised in rural France and the agricultural service established by the physicist of the observatory.

JAPAN has an active archæological society, bearing the title of Kobutzu-Kai (Society of Old Things). Its members, numbering 200, are scattered throughout the land, but meet once a month in Yeddo. They consist chiefly of wealthy Japanese gentlemen, learned men, and priests; the latter especially have been the means of bringing before public attention a vast number of ancient objects which have been hidden in the treasures of the temples, or preserved in private families. H. von Siebold, Attaché of the Austrian Embassy, at Yeddo, and a member of the society, has lately published a *brochure*, which will serve as a guide for the systematic archæological study of the land; von Siebold has lately made a most interesting discovery of a prehistoric mound at Omuri, near Yeddo, containing over 5,000 different articles in stone, bronze, &c. In a recent communication to the Berlin Anthropologische Gesellschaft, he describes the origin of the terra-cotta images found in old Japanese burial grounds. It appears that up to the year 2 B.C. it was the custom to surround the grave of a dead emperor or empress with a number of their attendants, buried alive up to the neck, their heads forming a ghastly ring about the burial spot. At the date referred to the custom was abolished, and the living offerings were replaced by the clay figures, which have hitherto attracted so much attention.

THE new ethnographical museum in the Palais de l'Industrie, at Paris, was opened on Wednesday last week, the Minister of Public Instruction pronouncing the opening discourse. Deputations were present from all the learned bodies and public institutions of the city, and general satisfaction was expresssed at the admirable manner in which Baron de Watteville, the director, had accomplished his task of organisation and arrangement.

THE Bolton Corporation have just adopted plans for the Chadwick Museum to be erected in the Bolton public park at a cost of 5,000*l*. The amount was left by the will of Dr. Chadwick for this purpose upon condition that the Corporation provided a site. The architect is Mr. R. K. Freeman.

PROF. W. M. GABB writes as follows from Puerto Plata, Sto. Domingo, December 29:—In the issue of November 1 you quote a Paris correspondent of the *Times*, who says that the Madrid people deny the authenticity of the recent finding of the remains of Columbus safe in the Cathedral of Santo Domingo. Of course the Spaniards are not willing to acknowledge that they were hoaxed, but the fact is nevertheless beyond dispute. The remains of Christopher Columbus are to-day in Santo Domingo. Unfortunately I am not able now to send you the full data. Suffice it to say that the chain of evidence is complete and has been verified with all possible precaution. The cheat was perpetrated by a then member of the "Cabildo," who had the knowledge, the tact, and the unscrupulousness to perpetrate it successfully. The whole consular corps, all the Government officials, and all the better class alike of natives and foreigners at the time in Santo Domingo city are witnesses of the authenticity of the "find."

ON Monday afternoon a powerful shock of earthquake was felt in the island of Jersey. It was so strong as to cause houses to totter and bells to ring. Its course was from east to west. There was at the time a heavy gale from the south-west in the English Channel. At 11.55 A.M. the same day a shock, lasting about four seconds, was felt at Eastern Alderney. No doubt it was the same earthquake which was felt at Brighton, Blackheath, Fareham, and St. Leonards, as reported in yesterday's *Times*, and at Paris, Havre, and Rouen, as stated by the *Times* Paris correspondent. Mr. Dobson, writing to us from the Royal Victoria Hospital, Netley, Southampton, states that the first shock occurred there at seven minutes to twelve o'clock exactly, and lasted about five or six seconds. It was sufficiently strong to cause the door to shake with some violence, and many objects in the room continued to vibrate for a considerable time. The second shock occurred a few seconds afterwards, but lasted for a much shorter period. A shock was felt at Lisbon on Saturday, being the third shock during the present winter.

A CIRCULAR signed by Mr. Justin Winsor, librarian of Harvard College, Cambridge, Mass., informs us that it is proposed to issue by subscription a catalogue of scientific serial publications in all languages, which has been prepared by Mr. Samuel H. Scudder, librarian of the American Academy of Arts and Sciences, and formerly librarian of the Boston Society of Natural History, and well known for his various scientific publications. This work, which has double the extent of any existing list of the like kind, aims to include all society transactions and independent journals in every branch of natural, mathematical, and physical science, excepting only the applied sciences—medicine, agriculture, technology, &c. The different institutions or periodicals are arranged under the towns in which they are established or published, and the towns follow an alphabetical order under their respective countries. Cross references are given wherever desirable. The work will be printed in large octavo, will extend to almost 300 pages, and will be delivered, bound in cloth, to subscribers at four dollars the copy. Other copies will be printed on one side of the leaf—to be cut up for catalogue use—and will be delivered in folded sheets at five dollars the copy. Further details may be obtained from Mr. Winsor.

A SECOND edition of Dr. M. Foster's "Text-Book of Physiology," has been published by Messrs. Macmillan and Co. The work has been revised and enlarged, and a number of figures of instruments has been introduced.

IN a recent paper to the Göttingen Society of Sciences, M. Grinitz has compared what data he could obtain regarding the effects of the earthquake at Iquique on May 9 last year. Among other points, it appears that the wave travelled from Iquique to Hilo, in Hawaii, a distance of 5,526 nautical miles, in fourteen hours; which is at the rate of 670 feet per second. From this velocity the average depth of that portion of the ocean traversed can be calculated by Airy's or Russell's formulæ; it is found to be 2,324 fathoms. The wave had an unbroken course to Hilo, but not so to Honolulu, as it encountered the islands of Hawaii, Maui, &c. The average velocity to Honolulu was 654.5 feet per second; and the average sea-depth inferred is 2,219 fathoms. The corresponding numerical data for Apia, Lyttelton, Uskaroa, in New Zealand, Komaishi, in Japan, and other places, are given. (For the last-named a velocity of 679 feet per second was obtained.) On comparison with Hochstetter's results for the earthquake of 1868, and with direct sea-measurements there is seen to be a very fair agreement. Hochstetter's assertion is, on the whole, confirmed, that the velocity of the earthquake wave and the lunar tide wave are identical.

WE have received from Messrs. Hardwicke and Bogue the first volume of their illustrated publication, *Industrial Art*, a monthly review of technical and scientific education at home and abroad. We have carefully examined the work and can say that the text and illustrations run each other very hard for carrying off the palm of excellence. We are glad to gather from the evident success of the venture that the time has arrived when scientific matter is regarded as the natural and necessary accompaniment of a complete reference to art matters. The articles on technical education in France, Austria, and Germany are thoroughly well done.

WE are glad to be able to point to another instance of a collection of the papers of a scientific man during his lifetime. Following hard upon the appearance of Dr. Frankland's collected papers Dr. Lloyd, of Dublin, has published a volume of 500 pages (Longmans) containing his memoirs, reports, and addresses given from time to time, from his classical paper on Conical Refraction to his address delivered before the British Association in 1857. The volume is a very valuable one for a scientific library, for at different times Dr. Lloyd has directed his attention to optics, terrestrial magnetism, and meteorology, and not only have we here the original papers but a series of reports on the progress and present state of physical optics extending over nearly 150 pages somewhat after the style of Verdet's introductions to the various parts of his work.

THE first general meeting of the Institute of Chemistry of Great Britain and Ireland will be held at the rooms of the Chemical Society, Burlington House, Piccadilly, to-morrow, at 4 P.M., to receive the report of the Council. A balance-sheet will also be presented by the treasurer.

WE have received one more evidence of the revival of activity in Italy, in the shape of the first number of a new weekly journal, *La Rassegna Settimanale di Politica, Scienze, Lettere ed Arte*, in which a fair amount of space is devoted to science. It is published at Florence.

THE following is a simple method recommended by Dr. Günther of Berlin, of observing the reversal of the coloured lines of flame-spectra. A thin platinum wire about five ctm. long, is fixed with one end in a glass tube (as holder), and one or two ctm. from the glass it is bent round to a right angle, and inserted in the envelope of a Bunsen flame, so that the free end, held vertical, is heated to a white glow. Into the diametrically opposite part of the flame-sheath is brought a sodium salt. This colours the flame. You then look through a weakly-dispersing prism (the combinations used for direct vision spectroscopes serve best), and through the sodium flame, towards the glowing wire. Two things are observed, (1) the spectrum of the monochromatic sodium flame, which appears in the form of the flame; (2) the spectrum of the glowing wire, which appears as a coloured band, but is broken by the dark D-line. Other metallic spectra may also be shown in this way; only care must be taken that the coloration of the flame be very intense.

AT Hanover the skeleton of a mammoth has just been found, through some excavations which are being made for waterworks near the Ricklinger Becke. At present only the skull and a tusk have been brought to light, the latter having the circumference of a human leg. The fossils are lying at a depth of six metres.

THE publishing firm of Edouard Rouveyre, in Paris, announces the publication of a voluminous catalogue containing the titles, &c., of all those works, books, pamphlets, &c., which, in the period from October 21, 1814, down to July 31, 1877, have been prosecuted, suppressed, or confiscated, in France. It will appear in five parts, at two francs each.

AT the beginning of the year the new Royal Library of Stockholm, which has now been transferred to the new building at the Humlegaarden, was opened to the public. The new edifice was erected after the design of the architect, Herr G. Dahl, at a cost of 900,000 Swedish crowns. The library, which at the beginning of the present century only numbered 30,000 volumes, now contains 200,000.

A NEW monthly periodical, exclusively devoted to the art of photography and its various branches, is being published since January 1, by Messrs. Ad. Braun and Co., of Dornach. Each number contains an artistic photograph. The title of the new serial is *Die Lichtbildkunst*.

UNUSUALLY severe avalanches are reported this winter from Styria. In the neighbourhood of Hieflau one descended upon a railway train, crushing the carriages, and wounding a number, while at Neuberg another fell upon a châlet containing twelve persons, none of whom escaped.

IN the closing session of the German Chemical Society for 1877, Prof. Kekulé, of Bonn, was elected president, Professors Hofmann and Liebermann of Berlin, Prof. Fehling of Stuttgart, and Prof. Erlenmeyer of Munich vice-presidents. The Society elected also as honorary members the two physicists, Prof. Buff of Giessen, and Prof. Kirchhoff of Berlin, and Dr. Stenhouse of London. At the end of its first decade the German Chemical Society looks back upon a period of rapid growth in numbers and efficiency certainly unparalleled in the history of any society devoted to a special science. These results are due to several marked causes, which could well be imitated by other associations possessing analogous aims, viz., ease of admission, absence of entrance fee and smallness of the annual subscription, simplicity of the statutes, and rapidity and frequency in the publication of the proceedings. The number of members at present is 1,827, showing an increase of 229 during the year. Of these 206 reside in Berlin and 542 outside of Germany and Austria. The membership compares favourably with that of the older sister societies in London (952), and Paris (371). Although the annual payment is so small (15 marks) the society possesses a capital at present of 22,700 marks. During the past ten years the *Berichte* of the society have contained 3,726 communications, covering nearly 14,000 pages. A very complete index to this enormous amount of material will appear during the course of the present year, the compiler of which was selected by competition from among the twenty-nine applicants attracted by the unusually liberal appropriation of 5,000 marks for the work. In addition to the extensive chemical correspondence from America, England, France, Italy, Russia, Sweden, Switzerland, &c., the value of the *Berichte* in the future is to be increased by a complete series of abstracts on all papers appearing in German chemical periodicals. In the last number we notice a very full and interesting sketch of the late Prof. Oppenheim from the pen of Prof. Hofmann, as well as a detailed account of the Chemical Section at the German Association meeting at Munich by Prof. Lieber-

THE French Academy of Sciences numbers at present 63, three places being vacant by the deaths of Regnault, Becquerel, and Leverrier, the members being divided into eleven sections of six each. There are in addition ten French free academicians and eight foreign associates. The corresponding members, of whom there can be 100, are divided according to their nationality as follows:—France, 32; Germany, 19; Great Britain, 16; Russia, 6; Italy, 2; Austria, 1; Denmark and Sweden, 4; Switzerland, 4; Belgium, 2; United States, 3; Brazil, 1; and there are 11 vacancies.

THE additions to the Zoological Society's Gardens during the past week include a Common Fox (*Canis vulpes*), European, presented by Mr. George Fredericks; two Black Swans (*Cygnus atratus*) from Australia, presented by Capt. W. H. Eccles; Wood Owl (*Syrnium aluco*), European, presented by Mr. J. E. Lardet; a Common Magpie (*Pica caudata*), a Jackdaw (*Corvus monedula*), European, presented by Mr. G. E. Ladbury; a Hoary Snake (*Coronella cana*) from South Africa, presented by the Rev. G. H. R. Fiske, C.M.Z.S; a Jackass Penguin (*Spheniscus magellanicus*), an Upland Goose (*Bernicla magellanica*) from Chili, two West Indian Rails (*Aramides cayennensis*) from South America, purchased; a Derbian Opossum (*Didelphys derbianus*) from South America, deposited; a Hog Deer (*Cervus porcinus*) born in the Gardens.

RAINFALL IN INDIA

WE have received so many long letters from India on the various aspects of the rainfall question that we must either, from want of space, leave them unpublished, or briefly give the gist of them. We adopt the latter course.

Mr. Archibald sends us a long letter on the seasonal rainfalls of Northern India in connection with the sun-spot period, in which he communicates a few of the principal results obtained from a more detailed and extensive comparison, which the paucity of data at his command hitherto had rendered it impossible to undertake. In the present investigation the registers of eight stations, four in Bengal, and four in the N.W.P. have been employed, and the two seasonal falls of each year, compared (1) for each station separately, and (2) for groups of four and all together, with its position in the sun-spot cycle.

The stations and the periods over which their registers of summer and winter rainfall respectively extend are as follows :—

		Summer rainfall. Years.	Winter rainfall. Years.
Bengal.	Calcutta	43	44
	Dacca	24	25
	Hazaribagh	15	15
	Patna	18	19
N.W.P.	Dehra Dun	16	18
	Roorkee	16	18
	Meerut	15	17
	Benares	15	17

"When the deviations from the local average seasonal falls in each year are calculated for each of the above stations separately, and the average taken for each year of the sun-spot cycle, it is found, notwithstanding individual irregularities which occur chiefly in the summer falls, (1) that the winter rainfalls uniformly exhibit a marked tendency to vary *inversely* with the sun-spots at all the stations, (2) that the summer rainfalls show a corresponding tendency to vary *directly* with the sun-spots, which, though strongly marked at the stations in the N.W.P., is scarcely perceptible at the Bengal stations. The result is best seen by combining several of the stations together, and since, owing to the large differences between the actual amount of rainfall at different stations, it is impossible to combine the deviations from the local averages, registered in inches, I have arranged the latter in the form of percentages of their respective averages, then multiplied each percentage deviation in each year of the sun-spot cycle by the number of years corresponding to it at each station, added the several products for the same year, and divided by the sum of the multipliers. By this means each station contributes to the final result in proportion to the extent of its register." Mr. Archibald then gives the tabulated results of combining according to this method (1) the four Bengal stations, (2) the four N.W.P. stations, and (3) all together.

From these tables it is seen that with very few exceptions the inverse relation between the two seasonal falls is strongly manifested throughout, the winter rainfall generally tending to rise above the average in proportion as the summer rainfall tends to fall below the same, and *vice versâ*. The winter rainfall moreover in every case tends to rise to a single maximum exactly coinciding with the period of minimum sun-spot, descending thence to a single minimum which occurs a year or two after the period of sun-spot maximum. The summer rainfall on the other hand exhibits two maxima and minima, and though varying more or less directly with the spots, this variation is principally confined to the N.W.P. stations.

The preceding peculiarities may be rendered still more apparent if we take as a new mean for each year of the cycle the mean of the mean percentage of the year itself together with half that of the preceding and succeeding years.

On the whole it is evident (1) that the winter rainfall throughout Northern India as well as at Calcutta is subject to a periodic variation amounting to nearly 50 per cent. of the average winter fall and corresponding approximately with the inverse phases of sun-spot frequency ; (2) that the variation in the summer rainfall, though relatively much smaller, is of an almost exactly opposite character, and that while well-marked in the N.W.P., it is scarcely appreciable in Bengal ; (3) that from the last table the cycle may be divided into two distinct portions, viz., the five years preceding, and the six years succeeding, the year of sun-spot maximum. In the former the winter rainfall is excessive and the summer rainfall defective, while in the latter the inverse relations hold, a fact somewhat analogous to the periodic change in the direction of the wind at Oxford and Prague as recently determined by Messrs. Main and Hornstein.

It is scarcely possible at present to indicate the practical deductions that may arise from a consideration of the preceding data. One inference, however, would appear to be immediately deducible, viz., that in any future comparison of the rainfalls of Northern India and other countries similarly subject to distinct seasonal rainfalls, due to distinct aerial currents—such as the monsoon and the anti-trade winds—with the sun-spot period, the summer and winter falls should be compared separately, otherwise it may be found that the combined effect of two opposite seasonal variations renders the resultant variation in the total annual fall very insignificant, or perhaps obliterates it altogether.

With reference to Mr. Hill's letter in NATURE, vol. xvi. p. 505, Mr. Blanford writes that he learns that Mr. Hill was not aware of the existence of his (Mr. Blanford's) paper in the forty-fifth volume of the *Journal* of the Asiatic Society of Bengal (1875), "hence, perhaps, what I cannot but regard as his under-estimate of the extent and validity of the evidence opposed to his view. He discusses the registers of three stations, one in the North-west Himalaya, and two on the dry plains of the Upper Gangetic Valley. My conclusions were based on the data of eleven stations altogether, viz., one in Roorkee, which is also selected by Mr. Hill, and one in Behar ; one on the Eastern Himalaya, one on the plateau of Western Bengal, one in Orissa, one in the Andaman Islands, and the remainder in Lower Bengal and Cachar. Moreover, I was careful to eliminate all errors arising from the use of different uncompared instruments ; and how necessary such a proceeding is, I illustrated by the remark that I have known sun-thermometers bearing the names of the best London makers differing 10° and 15° in their indications when exposed side by side under similar conditions to the sun. This precaution Mr. Hill has not taken, and I think his results are probably in a great measure due to that fact." Mr. Blanford thinks the sudden changes in the Roorkee register may be accounted for by the fact that the thermometer was twice changed, and the apparent increase in the wind's velocity by the shifting of the anemometers at Benares and Hazaribagh.

With respect to what Mr. Hill has said of the elements of error probably inherent to the method of discussion which Mr. Blanford adopted, while he admits the great difficulty there is in eliminating the effect of disturbing causes, he cannot admit that any *systematic* error was introduced, in the way suggested by Mr. Hill.

Mr. Blanford concludes :—"While on this subject I would direct attention to the importance of regular actinometric observations, of an absolute not merely relative character (such as are shown by the ordinary sun thermometers). The importance of making the solar changes a part of meteorological study is now fully recognised, and it is understood that a trained photographer is about to be sent to India to take photographs of the sun, but if this is so, regular actinometric observation should certainly form a part of the work. The best place perhaps would be Leh, where the atmosphere is remarkably free from haze and dust, which is not the case on the plains of Upper India ; nor indeed, in dry weather, on the north-west Himalaya. At Leh, 11,500 feet above the sea, the radiation is most intense. Regular observations with the actinometer carried on for a few years at this place should satisfactorily decide the question of the variation of the sun's heat."

Mr. Blanford also sends a reply to the letter of "Old Madrassee" in NATURE, vol. xvi. p. 519. Mr. Blanford believes that to anyone who has seen or can readily refer to the report on the question of the periodical variation of the rainfall of Madras, it will be abundantly obvious either that "Old Madrassee" can never have seen that report or that he must have misinterpreted its whole purport and argument, and in his references to it, must have trusted to a somewhat unusually treacherous memory.

On the subject of solar radiation and sun-spots Mr. Hill writes that since his article (vol. xvi. p. 505) was written he has gone over the registers of four other stations at which solar thermometers have been in use for five or six years. The former method of treatment is not applicable to these on account of breaks in the registers and changes in the instruments ; but adopting suitable methods to compensate for this, the results are as given in the following table, which shows the variation of each year from the preceding one :—

Stations.	1869.	1870.	1871.	1872.	1873.	1874.	1875.	1876.
Benares	—	− 1°·0	—	+ 0°·4	+ 1°·9	− 5°·8	+ 3·3	+ 2°·0
Gorakhpur	− 0·6	—	—	+ 1·0	+ 0·9	− 0·4	− 2·7	− 1·5
Ranikhet	—	—	—	+ 0·4	− 3·2	6·1	− 3·3	+ 2·9
Ajmere	—	− 2·0	+ 2·0	+ 1·7	+ 12·1	+ 3·2	− 4·7	− 0·3
Me	− 0·6	− 1·5	+ 2·9	+ 0·9	+ 2·9	− 2·3	− 1·8	+ 0·8

Owing to inequalities in the number of months combining to give the averages in the table, and to variations in the number of clear days in each month, the changes from year to year are very irregular, but on the whole there is a decided increase from 1870 to 1876. The sudden fall from 1873 to 1874 must be attributed, Mr. Hill thinks, to the greater diathermancy of the clear air at three of the stations in the former than in the latter year. It is worthy of note that 1873 was a very dry year at all the stations, but that 1874 was much wetter than usual except at Ajmere, where it was drier than 1873. At this station the solar radiation temperature shows a rise instead of a fall between 1873 and 1874.

With regard to the change of anemometer referred to by Mr. Blanford, Mr. Hill says that fortunately, in the present case, any other pair of stations, such as Madras and Vizagapatam, will do as well. With reference to the possible variation of the winter rain of Europe according to the supposed variation in the force of the anti-trade, Mr. Hill notices that the rainfall of London shows such a variation, though not very clearly. He adduces some figures in support of this.

In Mr. Hill's paper, vol. xvi., the word *minimum*, p. 505, second column, eighteenth line from bottom, *cases*, same column, third line from bottom, and *commutative*, p. 506, first column, fourth line from bottom, should be *maximum*, *excess*, and *cumulative* respectively.

Mr. Hill also writes that the large double oscillation in the decennial period of rainfall in Southern India, pointed out by Mr. J. A. Broun, in NATURE, vol. xvi. p. 333, will probably be found to exist in other parts of the country, including the north. One of the longest continuous registers of rainfall in existence for any station in Upper India is that kept by the G.T. Survey Office at Mussoorie, in the Himalayas, lat. N. 30° 28′, long. E. 78° 7′, altitude 6,500 feet. The rain has been recorded since 1854, but only during the rainy season, May to October, inclusive; and the register down to 1873 has been already published by Mr. J. B. N. Hennessey, in the *Proc. R.S.*, vol. xxii No. 152. Mr. Hennessey's table, extended down to the present year by means of a register kept by the Civil Surgeon, gives a general mean for the twenty-four years of 83·2 inches, and an absolute range of no less than 104 inches.

When the yearly rainfalls are arranged in series of two, three, &c., up to twelve years each, beyond which number it is impossible to extend the series without taking as representative the uncorrected falls of single years, it becomes evident that the great periodic oscillation that underlies the irregular variations must complete its cycle in from nine to twelve years, for the 9-, 10-, 11-, and 12-year series, all show a large amplitude of oscillation, and in the 11-year series the maximum and minimum occur at nearly opposite phases of the cycle. It is also evident that in the 6-year series the conditions are the same, the only difference being that the amplitude does not appear quite great

Calculating the coefficients of the equation of sines for the ten-and-a-half-year period, as Mr. Broun has done, we get for the variable part of the Mussoorie rainfall—

$$y = 11{\cdot}4 \sin \theta + 14{\cdot}0 \sin (2\theta + 337^\circ).$$

This may be compared with the equations given in Mr. Broun's article for Madras and Trevandrum,[1] for in all these equations $\theta = 0$ for the years 1838·5, 1849, 1859·5, 1870, &c. The difference of the two angles, 259° and 337°, causes a difference of more than a year in the epochs of the maxima and minima of the secondary oscillations, otherwise there is a wonderful similarity between the formulæ for two such widely-separated stations as Mussoorie and Trevandrum.[2]

Mr. Hill thinks it most likely that the oscillation of the five-yearly period is either purely accidental or the effect of some cause not yet understood.

Mr. Archibald, writing on the subject of Cyclone Generation, directs attention to an exceedingly interesting article in the *Pioneer* of October 30, entitled "A Cyclone Study," in which the author brings forward some very strong additional proof in confirmation of the "condensation theory" held by Messrs. Eliot and Blanford as opposed to the "parallel wind theory" advocated by Drs. Hann and Thau, and Messrs. Meldrum and Willson. After giving a clear account of the main points of difference between the above theories, the writer then proceeds to trace the history of the last cyclone in the Bay of Bengal, the Madras cyclone of May last, from its origin to its final disappearance, pointing out certain circumstances as giving strong support in favour of the condensation theory, and as completely disposing of the parallel wind theory—at all events as far as regards this particular cyclone.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Mathematical Tripos' list this year contains ninety-four names. There are thirty-one classed as Wranglers, thirty as Senior Optimes, twenty-nine as Junior Optimes, and four Ægrotant. The Senior Wrangler is Mr. Ernest William Hobson, Scholar of Christ's College, eldest son of Mr. W. Hobson, proprietor and editor of the *Derbyshire Advertiser*. He was educated at Derby School, and in 1874 obtained an open scholarship at Christ's College. During his undergraduate career he obtained the first place among the students in the college examinations in mathematics. His college tutor was Mr. Peile, and his private tutor Mr. E. J. Routh, of St. Peter's College. Next to him are Mr. John Edward Aloysius Steggall, scholar of Trinity College, and Mr. Christopher Graham, scholar of Caius.

During the present term three courses of lectures on chemistry will be delivered. A general course by Mr. Main at St. John's College; a course by Mr. Lewis at Downing College; and a course on the non-metallic elements by Mr. Pattison Muir at Caius College.

MUNICH.—The university is becoming in point of numbers one of the foremost in Germany. The calendar for the present year shows an attendance of 1,360, of whom 1,014 are from Bavaria and 346 from other countries. In the theological faculty there are 82, in the legal 387, in the medical 341, in the philosophical (history, philology, &c.) 246, (science) 151, together with 136 pharmaceutical chemists, and 17 in forestry and agriculture. The corps of instructors numbers 114. The university, although but fifty-two years old, has been well supported by the State, and possesses a large variety of laboratories, cabinets, &c., and a library of 20,000 volumes.

SOCIETIES AND ACADEMIES

LONDON

Royal Astronomical Society, January 11.—Dr. Huggins, F.R.S., in the chair.—A paper by Mr. W. F. Denning on suspected repetitions or second outbursts from radiant points, and on the long duration of meteor showers, was read, showing that a radiant in some cases continues active during three or four months, and sometimes a second outburst occurs after an interval of six months, so that meteors may be seen coming from the same radiant at opposite sides of the earth's orbit. Capt. Tupman commented on this paper at some length, and pointed out some of the difficulties these conclusions presented.—Dr. Wentworth Erck read a paper on a combined position and setting circle, rendering the declination circle unnecessary on large Newtonian equatorials. He also showed a small and singularly portable equatorial mounting, and read a note on a spectroscope made by Mr. Grubb for Prof. Young, showing certain improvements. Mr. John Browning admired the ingenuity of these, and explained which of them were new and which were not.—Mr. A. A. Common read a note on the satellites of Mars and Saturn.—A note was read describing the failure of the Melbourne telescope to deal with the satellites of Mars.—Mr. S. Waters read a paper on the distribution of the fixed stars in space.—Mr. Christie read a paper on specular reflection from Venus, the purport of which was that his recent observations of the planet with the polarising eye-piece emphatically corroborated those made in 1876. By means of this eye-piece the light of the disc is gradually reduced; and he found in every examination that the last part of the disc to disappear was situated at a point which was found by calculation to coincide with the point indicated by the theory of specular reflection, thus confirming Mr. Brett's original description of the phenomenon. Mr. Christie had the assistance of Capt. Tupman in his recent observations. Mr. Neison suggested certain other explanations of the appearances described, and after further discussion the meeting adjourned.

Zoological Society, January 15.—R. Hudson, F.R.S., vice-president, in the chair.—A communication was read from Mr.

---

[1] Viz.: $y = 5{\cdot}4 \sin (\theta + 50^\circ) + 4{\cdot}6 \sin (2\theta + 252^\circ)$,
and $y = 5{\cdot}6 \sin (\theta - 17^\circ) + 8{\cdot}4 \sin (2\theta + 259^\circ)$.

[2] The above equation for Mussoorie gives the maxima in 1860·3, 1870·8, &c., and the minima in 1857·2, 1867·7, &c. The first term alone would give the maxima in 1860·1, 1870·6, &c., and the minima in 1855·9, 1866·4, 1876·9, &c.

Andrew Anderson, F.Z.S., containing some corrections and additions to a former paper of his on the raptorial birds of the north-west provinces, read before the Society on March 21, 1876.—A communication was read from Mr. F. Moore, F.Z.S., containing a revision of the genera and species of European and Asiatic lepidoptera belonging to the family Lithosiidæ. The author characterised thirty-eight genera in this memoir, and gave the descriptions of eighty new species.—Mr. A. Boucard, C.M.Z.S., read a paper in which he gave a list of the birds he had collected during a recent expedition to Costa Rica. The number of birds collected during his five months' stay was about one thousand in number, representing 250 species, amongst which were two new to science (*Zonotrichia boucardi* and *Sapphironia boucardi* of Mulsant) and many others of great rarity.—Two papers were read by Mr. G. French Angas. The first contained descriptions of seven new species of land shells recently collected in Costa Rica by M. A. Boucard. The second contained the description of a new species of *Latiaxis* from an unknown locality, proposed to be called *L. elegans*.—A communication was read from Dr. H. Burmeister, containing notes on *Conurus hilaris* and other parrots of the Argentine Republic.—A communication was read from the Count Salvadori, C.M.Z.S., in which an account was given of the birds collected during the voyage of H.M.S. *Challenger*, at Ternate, Amboyna, Banda, the Ké Islands, and the Aru Islands.—Prof. Garrod, F.R.S., read a paper on certain points in the anatomy of the Momotidæ, in which he adduced facts substantiating their affinities with the Todidæ, Alcedinidæ, and other Piciformes. The second paper described the extraordinary structure of the gizzard of the Fijian Fruit Pigeon (*Carpophaga latrans*), in connection with the fruit on which it feeds, that of *Oncocarpus vitiensis*.—A communication was read from Mr. Edgar A. Smith, F.Z.S., containing the description of a new species of Helix from Japan, which he proposed to call *Helix* (*Camena*) *congener*.—A communication was read from the Marquis of Tweeddale, F.R.S., containing an account of a collection of birds made by Mr. A. H. Everett in the Philippine Islands of Dinagat, Bazol, Nipak, and Sakeryok. Six new species were found in this collection and were named *Ceyx argentata*, *Hypothymys cœlestis*, *Mixornis capitalis*, *Dicæum schistaceum*, *D. everetti*, and *Prionochilus olivaceus*.—A second paper by the Marquis of Tweeddale gave the description of a new genus and species of bird from the Philippine Island of Negros, for which the name *Dasycrotapha speciosa* was proposed.

Photographic Society, January 8.—James Glaisher, F.R.S., president, in the chair.—Papers were read by Capt. Abney, F.R.S., on the theory of the destruction of the undeveloped photographic image; by Edward Viles, on the production of enlarged photographs of microscopic objects; and by Edwin Cocking, "stray thoughts on the exhibition."—Capt. Abney in his paper stated the result of experiments undertaken to ascertain the cause of the fading away of the undeveloped image on dry plates by long keeping after exposure. Films of pure silver iodide, and of pure silver bromide, after exposure, were washed with potassium permanganate, potassium bichromate, and chromic acid; with the silver iodide salt, *all* destroyed the image, with the silver bromide salt the last two oxidising agents alone were effective. If this destruction of the image was caused by oxidation of the silver atom, it should also be oxidised by ozone—which experiments showed was the case. Capt. Abney then assumes that the effect of time on the image on a dry plate is to oxidise an atom of each of the molecules forming the image.

Institution of Civil Engineers, January 15.—The newly-elected president, Mr. John Frederic Bateman, F.R.SS.L. and E., delivered an inaugural address. After a passing allusion to the growth of the Institution, which at the end of 1844 numbered only 552 of all classes, now increased to 3,189, reference was made to some of the addresses of the eighteen gentlemen who had previously occupied the presidential chair, mainly for the purposes of comparison. Proceeding to matters more personal to every member of the Institution, the President urged that engineering was but, in fact, the embodiment of practical wisdom; or, in the words of Bacon, "the conjunction of contemplation and action."

EDINBURGH

Royal Society, January 7.—Bishop Cotterill, vice-president, in the chair.—Prof. Blackie read a paper on Mr. Gladstone's theory of colour-sense in Homer, which he completely refuted. A discussion followed, in which Principal Sir Alexander Grant, Bart., the Rev. Dr. Cazenove, Prof. Fleeming Jenkin, Dr. Donaldson, and others took part.—Prof. Tait postponed his paper on the intensity of currents required to work the telephone but mentioned that Mr. James Blyth had obtained good results with telephones in which he had employed discs of copper-wood vulcanised india-rubber paper, instead of the usual iron ones.—Prof. Tait also laid on the table a double mouthed-piece horn for producing chords by two performers on the same instrument.

VIENNA

Imperial Academy of Sciences, November 16, 1877.—On ice in the Danube in Lower Austria, in the winter 1876–77, by the Minister of the Interior.—Researches on the consciousness of place and its relation to the conception of space, by M. Stricker.—On the temperature of Vienna according to 100 years' observations, by M. Hann.—On the phanerogam flora of the Hawaii Islands, by M. Reichardt.

November 22, 1877.—On a partial differential equation of the first order, by M. Hocevar. The laws of the individuality of the planets of our solar system; attempt to establish a general theory, by M. Lehmann.

December 6, 1877.—The velocity of propagation of spark waves, by MM. Mach, Tumlirz, and Kögler.—On the application of Doppler's principle to the progressive motion of luminous gas molecules, by M. Pfaundler.—On some problems of the theory of elastic reaction, and on a new method of observing vibrations by reading of mirrors, without loading the vibrating body with a mirror of considerable size, by M. Boltzmann.—Determination of surfaces any of whose parts, from two fixed points, are projected through cones the apertures of which are in a given proportion, by M. Weyr.—On mononitrobrenzcatechin, by M. Benedikt.—Size and position of the optical axes of elasticity in gypsum, by M. von Lang.—On the orbit of the planet Laurentia (162), by M. Zelbr.

PARIS

Academy of Sciences, January 21.—M. Daubrée in the chair.—On account of the death of MM. Becquerel and Regnault, the *séance* was adjourned. The funeral of M. Becquerel took place the same day, that of M. Regnault next day. Discourses on the former were pronounced by MM. Fizeau and Daubrée; on the latter by MM. Debray, Jamin, Daubrée, and Laboulaye. [These are reported in the *Comptes Rendus* for the week.]

THE SOCIETY OF TELEGRAPH ENGINEERS

WHEN a society which numbered 110 members at the date of its first public meeting can, after an existence of only six years, count 1,000 names upon its books, it has at least justified its existence, and those who have taken the chief part in calling it into being and guiding its course, may fairly consider that the numbers who have sought association with them prove that their proceedings have been, at any rate, not injudicious. It was, therefore, with good reason, that Dr. C. W. Siemens began his address to the Society of Telegraph Engineers on the occasion of his re-election to the office of President, by congratulating the society on the progress made by it since he addressed it in the capacity of its first President on February 28, 1872.

In these congratulations we heartily join, and we think that no one will question the wisdom of the society in calling back to the Presidentship a man who did so much in the early days of its career to prepare the way for the success since realised.

The claim of the Society of Telegraph Engineers to rank as a scientific institution cannot, however, be founded upon the mere number of its members, nor even on the scientific eminence of some of the names to be found in the list. Its scientific position must of course be judged of by considering, not how many or who its members are, but what they do in their associated capacity for the advancement of science. Ample materials for forming such an estimate as this are afforded by the six substantial volumes already published of the *Journal* of the Society of Telegraph Engineers. These volumes contain the papers communicated to the Society and reports of discussions at the meetings, and in addition a considerable number of reprints or abstracts of papers published elsewhere, bearing on the objects pursued by the Society. As might be expected in the case of a society founded primarily to promote the advancement, not of abstract science, but of a branch of industrial enterprise, papers of a so-called "practical" kind are the most numerous, and, if we may judge from the reported discussions, papers of this class are those which call forth the most general interest at the Society's meetings. But even among such papers, embodying as they usually do the results of careful observation and long experience on the matters of which they treat, there are few from which the student of physics may not gather some hint of value. There are, however, a considerable number of papers of which the scientific bearing is more direct. These are papers which, dealing with questions arising primarily out of the practice of the telegraph engineer, treat the problems discussed from the point of view afforded by the general scientific principles applicable to them, or which contain results of no less scientific than practical value. Among papers of this class, one by Mr. Hockin (vol. v. pp. 432-459) on "The Magnitude of Signals received through a Submarine Cable with various Connections at each end, and the best Resistance for the Recording Instrument," is specially deserving of mention. It contains a very masterly treatment of what is in reality a purely scientific problem, though one which has very direct practical importance. And here we may digress for a little in order to point out that this paper of Mr. Hockin's affords an instructive illustration of the mutual beneficial interaction between "theory" and "practice" of which the whole history of the electric telegraph is full. The telegraph is in a fuller degree than most practical inventions the direct outcome of scientific investigation, but when, in the progress of telegraphic enterprise, the project arose of laying long submarine lines, it was found that, though the general nature of the electrical difficulties to be encountered was known, yet the scientific knowledge of the time was not sufficient to indicate clearly the way in which they were to be overcome, and from the nature of the case but little help was forthcoming from empirical experience. The matter was in this state when Sir William Thomson took up the question of the transmission of signals through submarine telegraph cables, and showed how the practical message-carrying power of an insulated conductor laid under water is connected with the dimensions and certain definite electrical qualities of the conductor and its insulating coating. The conclusions which he arrived at mathematically as long ago as 1855 have since remained the foundation of all successful practice in the manufacture of telegraph cables. Sir W. Thomson, however, took account only of the properties of the cable itself, whereas in the actual working of submarine telegraphy very much depends upon the proper selection and arrangement and adaptation to each particular cable of the sending and receiving apparatus employed at the two ends; and what Mr. Hockin has now done is to give a general theory which takes account of the electrical properties of the instruments as well as of the cable. Returning to the *Journal* of the Society of Telegraph Engineers, we may mention a short paper by Mr. Sabine on the Capacity of Accumulators Variously Combined, one by Sir William Thomson on the Comparison of Electrostatic Capacities, and a note by Prof. Maxwell on the Theory of Lightning Conductors, among the original articles, as well as Messrs. Longridge and Brooks's paper on the Submergence of Telegraph Cables and Mr. Schwendler's on the Theory of Duplex Telegraphy, among the reprints, as examples which afford further proof that the Society, is established for practical objects, is not blind to the aid to be derived in the pursuit of those objects from the study of scientific principles. And although we do not suppose that all the 1,000 members study such papers as we have referred to with great eagerness, yet the mere fact of their circulation must do something to convince the most arrogantly "practical" man among them that ignorance is not in all respects a ground for thankfulness.

So far this flourishing society has professedly occupied itself only with telegraphy, but there are not wanting signs either in the Journal or in Dr. Siemens's address, of the difficulty of separating telegraphy from other departments of what may be called applied electricity. Thus, more than one paper has been read to the society upon the application of electricity to firing mines and torpedoes, an operation which, when successfully performed, generally results in causing the persons affected to dispense permanently with telegraphic communication, and Dr. Siemens devotes nearly a quarter of his address

VOL. XVII.—No. 432

to discussing the application of electricity for illuminating purposes, to the transmission of motive power, and in metallurgic processes. Recent improvements in the means of obtaining powerful electric currents seem to open up a prospect of such applications as those just mentioned, assuming in the near future greater practical importance than they have hitherto possessed, and it does not seem unlikely that, whether or not they think fit to assume the wider designation, the Society of Telegraph Engineers will have become a Society of Electrical Engineers.

G. C. F.

TAIT'S "THERMODYNAMICS" [1]

II.

Sketch of Thermodynamics. By P. G. Tait, M.A., formerly Fellow of St. Peter's College, Cambridge, Professor of Natural Philosophy in the University of Edinburgh. Second Edition, revised and extended. (Edinburgh: David Douglas, 1877.)

PROF. CLAUSIUS is himself the principal founder of the kinetic theory of gases. The theory of the exchanges of the energy of collections of molecules was afterwards developed by Boltzmann to a much greater extent than had been done by Clausius, and it appears from his investigations that whether we suppose the molecules to be acted on by forces towards fixed centres or not, the condition of equilibrium of exchange of energy, or in other words the condition of equality of temperature of two bodies, is that the average kinetic energy of translation of a single molecule is the same in both bodies.

We may therefore define the temperature of a body as the average kinetic energy of translation of one of its molecules multiplied into a constant which is the same for all bodies. If we also define the total heat of the body as the sum of the whole kinetic energy of its molecules, then the total heat must be equal to the temperature multiplied into the number of molecules, and by the ratio of the whole kinetic energy to the energy of translation, and divided by the above constant.

The kinetic theory of gases has therefore a great deal to say about what Rankine and Clausius call the actual heat of a body, and if we suppose that molecules never coalesce or split up, but remain constant in number, then we may also assert, all experiments notwithstanding, that the real capacity for heat (as defined by Clausius) is constant for the same substance in all conditions.

Rankine, indeed, probably biased by the results of experiments, allowed that the real specific heat of a substance might be different in different states of aggregation, but Clausius has clearly shown that this admission is illogical, and that if we admit any such changes, we had better give up real specific heat altogether.

Statements of this kind have their legitimate place in molecular science, where it is essential to specify the dynamical condition of the system, and to distinguish the kinetic energy of the molecules from the potential energy of their configuration; but they have no place in thermodynamics proper, in which we deal only with sensible masses and their sensible motions.

Both Rankine and Clausius have pointed out the importance of a certain function, the increase or diminution of which indicates whether heat is entering or leaving the body. Rankine calls it the thermodynamic function, and Clausius the entropy. Clausius, however, besides inventing the most convenient name for this function, has made the most valuable developments of the idea of entropy, and in particular has established the most important theorem in the whole science,—that when heat passes from one body to another at a lower temperature, there is always an increase of the sum of the entropy of the two bodies, from which it follows that the entropy of the universe must always be increasing.

He has also shown that if the energy of a body is expressed as a function of the volume and the entropy, then its pressure (with sign reversed) and its temperature are the differential coefficients of the energy with respect to the volume and the entropy respectively, thus indicating the symmetrical relations of the five principal quantities in thermodynamics.

But Clausius, having begun by breaking up the energy of the body into its thermal and ergonal content, has gone on to break up its entropy into the transformational value of its thermal content and the disgregation.

Thus both the energy and the entropy, two quantities capable of direct measurement, are broken up into four quantities, all of them quite beyond the reach of experiment, and all this is owing to the actual heat which Clausius, after getting rid of the latent heat, suffered to remain in the body.

Sir William Thomson, the last but not the least of the three great founders, does not even consecrate a symbol to denote the entropy, but he was the first to clearly define the intrinsic energy of a body, and to him alone are due the ideas and the definitions of the available energy and the dissipation of energy. He has always been most careful to point out the exact extent of the assumptions and experimental observations on which each of his statements is based, and he avoids the introduction of quantities which are not capable of experimental measurement. It is therefore greatly to be regretted that his memoirs on the dynamical theory of heat have not been collected and reprinted in an accessible form, and completed by a formal treatise, in which his method of building up the science should be exhibited in the light of his present knowledge.

The touchstone of a treatise on thermodynamics is what is called the second law.

Rankine, as we have seen, founds it on statements which may or may not be true, but which cannot be considered as established in the present state of science.

The second law is introduced by Clausius and Thomson as an axiom on which to found Carnot's theorem that the efficiency of a reversible engine is at least as great as that of any other engine working between the same limits of temperature.

If an engine of greater efficiency exists, then, by coupling this engine with Carnot's engine reversed, it is possible to restore to the hot body as much heat as is taken from it, and at the same time to do a certain amount of work.

If with Carnot we suppose heat to be a substance, then this work would be performed in direct violation of the first law—the principle of the conservation of energy. But if we regard heat as a form of energy, we cannot apply this method of *reductio ad absurdum*, for the work may be derived from the heat taken from the colder body.

---

[1] Continued from p. 259.

Clausius supposes all the work gained by the first engine to be expended in driving the second. There is then no loss or gain of heat on the whole, but heat is taken from the cold body, and an equal quantity communicated to the hot body, and this process might be carried on to an indefinite extent.

In order to assert the impossibility of such a process in a form of words having sufficient verisimilitude to be received as an axiom, Clausius, in his first memoir, simply says that this process "contradicts the general deportment of heat, which everywhere exhibits the tendency to equalise differences of temperature, and therefore to pass from the warmer to the colder body." [1]

In its obvious and strict sense no axiom can be more irrefragable. Even in the hypothetical process, the impossibility of which it was intended to assert, every communication of heat is from a warmer to a colder body. When the heat is taken from the cold body it flows into the working substance which is at that time still colder. The working substance afterwards becomes hot, not by communication of heat to it, but by change of volume, and when it communicates heat to the hot body it is itself still hotter.

It is therefore hardly correct to assert that heat has been transmitted or transferred from the colder to the hotter body. There is undoubtedly a transfer of energy, but in what form this energy existed during its middle passage is a question for molecular science, not for pure thermodynamics.

In a note added in 1864 Clausius states the principle in a modified form, "that heat cannot of itself pass from a colder to a warmer body" [2] and finally, in the new edition of his "Theory of Heat" (1876 he substitutes for the words "of itself" the expression "without compensation." [3]

With respect to the first of these emendations we must remember that the words "of itself" are not intended to exclude the intervention of any kind of self-acting machinery, and it is easy, by means of an engine which takes in heat from a body at 200° C., and gives it out at 100° to drive a freezing machine so as to take heat from water at 0°, and so freeze it, and also a friction break so as to generate heat in a body at 500°. It would therefore be necessary to exclude all bodies except the hot body, the cold body, and the working substance, in order to exclude exceptions to the principle.

By the introduction of the second expression, "without compensation," combined with a full interpretation of this phrase, the statement of the principle becomes complete and exact; but in order to understand it we must have a previous knowledge of the theory of transformation-equivalents, or in other words of entropy, and it is to be feared that we shall have to be taught thermodynamics for several generations before we can expect beginners to receive as axiomatic the theory of entropy.

Thomson, in his "Third Paper on the Dynamical Theory of Heat" (*Trans.* R.S. Edin., xx., p. 265 (read March 17, 1851) has stated the axiom as follows:—

"It is impossible, by means of inanimate material agency, to derive mechanical effect from any portion of matter by cooling it below the temperature of the coldest of surrounding objects."

Without some further restriction this axiom cannot be considered as true, for by allowing air to expand we may derive mechanical effect from it by cooling it below the temperature of the coldest of surrounding objects.

If we make it a condition that the material agency is to be left in the same state at the end of the process as it was at first, and also that the mechanical effect is not to be derived from the pressure of the hot or of the cold body, the axiom will be rendered strictly true, but this brings us back to a simple re-assertion of Carnot's principle, except that it is extended from heat engines to all other kinds of inanimate material agency.

It is probably impossible to reduce the second law of thermodynamics to a form as axiomatic as that of the first law, for we have reason to believe that though true, its truth is not of the same order as that of the first law.

The first law is an extension to the theory of heat of the principle of conservation of energy, which can be proved mathematically true if real bodies consist of matter "as per definition," acted on by forces having potentials.

The second law relates to that kind of communication of energy which we call the transfer of heat as distinguished from another kind of communication of energy which we call work. According to the molecular theory the only difference between these two kinds of communication of energy is that the motions and displacements which are concerned in the communication of heat are those of molecules, and are so numerous, so small individually, and so irregular in their distribution, that they quite escape all our methods of observation; whereas when the motions and displacements are those of visible bodies consisting of great numbers of molecules moving all together, the communication of energy is called work.

Hence we have only to suppose our senses sharpened to such a degree that we could trace the motions of molecules as easily as we now trace those of large bodies, and the distinction between work and heat would vanish, for the communication of heat would be seen to be a communication of energy of the same kind as that which we call work.

The second law must either be founded on our actual experience in dealing with real bodies of sensible magnitude, or else deduced from the molecular theory of these bodies, on the hypothesis that the behaviour of bodies consisting of millions of molecules may be deduced from the theory of the encounters of pairs of molecules, by supposing the relative frequency of different kinds of encounters to be distributed according to the laws of probability.

The truth of the second law is therefore a statistical, not a mathematical, truth, for it depends on the fact that the bodies we deal with consist of millions of molecules, and that we never can get hold of single molecules.

Sir William Thomson [1] has shown how to calculate the probability of the occurrence within a given time of a given amount of deviation from the most probable distribution of a finite number of molecules of two different kinds in a vessel, and has given a numerical example of a particular case of the diffusion of gases.

---

[1] Und das widerspricht dem sonstigen Verhalten der Wärme, indem sie überall das Bestreben zeigt, vorkommende Temperaturdifferenzen auszugleichen und also aus den wärmeren Körpern in die kälteren überzugehen.

[2] Dass die Wärme nicht von selbst aus einem kälteren in einem wärmeren Körper übergehen kann.

[3] Ein Wärmeübergang aus einem kälteren in einem wärmeren Körper kann nicht ohne Compensation stattfinden.

[1] "On the Kinetic Theory of the Dissipation of Energy," *Proc.* R.S. Edin., February 16, 1874, vol. viii. p. 323, also in NATURE, vol. ix. p. 441.

The same method might be extended to the diffusion of heat by conduction, and the diffusion of motion by internal friction, which are also processes by which energy is dissipated in consequence of the motions and encounters of the molecules of the system.

The tendency of these motions and encounters is in general towards a definite state, in which there is an equilibrium of exchanges of the molecules and their momenta and energies between the different parts of the system.

If we restrict our attention to any one molecule of the system, we shall find its motion changing at every encounter in a most irregular manner.

If we go on to consider a finite number of molecules, even if the system to which they belong contains an infinite number, the average properties of this group, though subject to smaller variations than those of a single molecule, are still every now and then deviating very considerably from the theoretical mean of the whole system, because the molecules which form the group do not submit their procedure as individuals to the laws which prescribe the behaviour of the average or mean molecule.

Hence the second law of thermodynamics is continually being violated, and that to a considerable extent, in any sufficiently small group of molecules belonging to a real body. As the number of molecules in the group is increased, the deviations from the mean of the whole become smaller and less frequent; and when the number is increased till the group includes a sensible portion of the body, the probability of a measurable variation from the mean occurring in a finite number of years becomes so small that it may be regarded as practically an impossibility.

This calculation belongs of course to molecular theory and not to pure thermodynamics, but it shows that we have reason for believing the truth of the second law to be of the nature of a strong probability, which, though it falls short of certainty by less than any assignable quantity, is not an absolute certainty.

Several attempts have been made to deduce the second law from purely dynamical principles, such as Hamilton's principle, and without the introduction of any element of probability. If we are right in what has been said above, no deduction of this kind, however apparently satisfactory, can be a sufficient explanation of the second law. Indeed some of them have already indicated their unsoundness by leading to determinations of physical quantities which have no existence, such as the periodic time of the alternations of the volume of particular gases.[1]

J. CLERK MAXWELL

OUR BOOK SHELF

Heroes of North African Discovery. By N. D'Anvers. (London: Marcus Ward and Co., 1877.)

MR. D'ANVERS has here made an interesting *résumé* of the work of the principal travellers who have made Africa known to the world. He briefly dismisses the earlier explorers, the bulk of the volume being devoted to those of the eighteenth and nineteenth centuries. Mr. D'Anvers has evidently read his authorities carefully, and gives a clear account of his heroes' adventures, and of the main results achieved. The book is evidently meant for young readers, and to them both the text and the numerous illustrations will prove attractive. But all who wish to have a fair knowledge of what has been hitherto achieved in the field of African discovery should read this interesting and instructive volume. The author prefixes a list of the authorities he has consulted, and promises another volume on South Africa, in which the results obtained by Mr. Stanley will be embodied.

Manual of Agriculture; including the Application thereto of Chemistry, Geology, Botany, Animal Physiology, and Meteorology. By Richard Henderson.

THIS is a reprint of one of the Highland Agricultural Society's prize essays. It forms a very marked exception from the thoroughly practical essays which are usually published by that society, so much so indeed, that it is a source of regret that a society which has done so much to improve agricultural education, should have in any way stamped the present work with its approval and authority.

The work is divided into seven chapters, of which five are devoted to some notices of chemistry, geology, botany, animal physiology, and meteorology, and the seventh alone treats upon the application of these sciences to agricultural practice, which is the professed subject of the work.

A few extracts from the first six chapters will given an idea of the character of this part of the work. The second chapter deals with chemistry, and is largely made up of comments upon eighteen elements, the descriptions being remarkably similar to those given by Roscoe in his "Lessons." It is fair to say that the author occasionally introduces original remarks, as, for instance, in saying that "carbon forms about fifty per cent. of the residue of plant-life when the latter is charred, and access of atmospheric air or oxygen prevented, for oxidised carbon escapes as a gas." Prof. Roscoe fares rather badly at the hands of our author, since he in another place says, "Roscoe gives the following graphic formula as the average composition of blood," and he appends the average percentage composition.

We are told again that at the sea-level the pressure of the air "can support a column of mercury thirty inches high in a tube *in vacuo*." Concerning fogs and mists, "they result from the radiation of heat from land and water, taking with it aqueous vapour, which becomes visible upon encountering cooler air. Similarly rain is produced when heated volumes of air are deprived of their heat, through the fall of condensed vapour, which assumes, according to the temperature it encounters, the form of hail, rain, or snow."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Sun-Spots and Terrestrial Magnetism

MR. B. G. JENKINS, in his letter to NATURE, vol. xvii. p. 260, says, "I have ventured to state my belief that we are now passing through a long minimum period, one very similar to that which occurred at the close of last century." It was the chief object of my communication to NATURE, vol. xvii. p. 183, to show the latter fact as far as the observations go up to the present time. I did not, however, venture in that article to make a guess as to the future, which really could have little weight till we have another year's observations. Yet I thought it desirable, nearly two months ago, to place in the hands of Prof. Balfour Stewart the evidence that the possibility of such an event, as an obvious conclusion from my results, had not escaped me. As Mr. Jenkins has published his guess, I may do the same with mine. The latter differs, however, from his in a very important way. He supposes the next maximum will be in 1887, whereas I suppose that the weak maximum of 1797 may be repeated near 1880. In this latter case the interval between the two will be nearly double that found by me (forty-two years), during which the sun-spot period appears to have all its different lengths.

February 1 JOHN ALLAN BROUN

Terrestrial Magnetism

I HEREWITH submit a notice of an experiment for illustrating to a class the action of terrestrial magnetism. In a simple way it clearly exhibits to a large audience the action of the currents of electricity that pass around the earth. The experiment was suggested on reading a paper by Prof. J. W. Mallet, F.R.S., of the University of Virginia, on "The Apparent Alteration in Weight of a Wire placed East and West, and Traversed by an Electric Current" (*Phil. Mag.*, November, 1877).

Instead of disconnecting the wires placed east and west from the portion of the rectangle, as was done by Prof. Mallet in the experiment alluded to, whereby the attractive or repulsive action of the earth currents on one side only of the rectangle was obtained, it occurred to me to suspend the whole rectangle to a balance. Properly arranged in this way the attraction for parallel currents in same direction, and repulsion for currents in opposite direction would generate a couple, tending to produce rotation around an east and west horizontal axis, and hence augment the deflection of the balance.

A rectangular frame was made of light poplar wood, of section three by two centimetres, whose sides were one metre in length by three-fourths of a metre in breadth. About the perimeter of this rectangle there were wrapped twenty coils of insulated copper wire. Each extremity of the wire was made to terminate near the centre of one of the shorter sides, and passing through the wooden frame, was fastened and cut off about 3 c.m. from the frame.

This rectangular frame was then so suspended, in a horizontal position, by wires attached to the pans of an ordinary Deleuil's hydrostatic balance, that the longer sides were at right-angles to the beam. By adjusting weights in the scale pans the index of the balance was brought to the zero. Two small orifices bored in a block of wood a centimetre apart, served as mercury cups, in which the extremities of the short terminal wires were immersed; near the bottom and through the walls of these wooden mercury-cups were screened small brass hooks, which served as connectors, to which the wires of the battery were attached. The balance was now so placed that the longer sides of the suspended rectangle were *at right-angles with the magnetic meridian*, or in the *magnetic* east and west line.

When the current from the battery was made to pass around the rectangle from east to west, on the northern side, and from west to east, on the southern side, by the theory of terrestrial magnetism, the north side of the rectangle would be attracted to the earth, and the south side repelled, and that this was so the corresponding deflection of the balance rendered plainly visible. When the current was reversed the deflection was in the opposite direction. By breaking and closing the circuit at proper intervals to augment the oscillations, the large frame was readily made to oscillate through an arc of 5°. When the sides of the rectangle were placed north-east and south-west, the current produced no sensible effect. A bichromate of potash battery of sixteen cells was used with plates of zinc and carbon 25 cm. by 6 cm.

With a rectangle containing a larger number of coils of wire attached to a delicate balance by the use of a *constant* battery, the variations in the earth's magnetism might be thus observed.

Seiches and Earthquakes

IN the last number of NATURE (p. 234) you make an allusion to the fact that the earthquake of October 8, 1877, has not been traced by the self-registering "limnimeters" (tide-gauge) of M. Ph. Plantamour at Geneva, and myself at Morges. Let me take the opportunity of the great publicity of your excellent paper to ask the naturalists who live in other countries more frequently visited by earthquakes, for an explanation.

I believe I have demonstrated in many different papers that the phenomenon called *seiches*, which consists in rhythmical movements of the level of the lake, is a balancing-wave, a wave of stationary uninodal oscillation. The water moves in balancing oscillation in the two principal diameters of the lake, in the direction of the greatest length and of the greatest breadth. For setting the water in such an oscillatory movement there are two possible causes:—

1. A shock given to the water itself is the most frequent case, and I can prove that generally the *seiches* are caused by some rupture of the equilibrium of the atmospheric pressure; many storms, and especially those that fall somewhat abruptly on the lake, are accompanied by very high *seiches*, and I have many examples of the beginning of the oscillatory movement of the water exactly at the same time the storm commences.

2. A movement of the soil on which the water lies, an earthquake. It is evident that a shock given to a basin can put the water in oscillatory movement. In fact, it happens frequently. I will only recall the colossal transmission-waves in the Pacific Ocean on August 13, 1868, after the earthquake of Arica; that of May 9, 1877, at Iquique; and in earlier times, the earthquakes at Messina, 1783; at Port-Royal (Jamaica), 1692; at Callao, 1586, &c. If such enormous waves had taken place in a closed basin, as our lakes, it would probably have brought about an oscillatory movement of *seiches*. I could bring many facts to prove it; only one example, the earthquake of Lisbon (1755), was noticed in Switzerland and Germany, chiefly by the movements of the water of the lakes; the description of these movements recalls perfectly the *seiches*.

It is also theoretically probable that the shock given to the ground extends to the waters, and that an earthquake will produce *seiches* in a lake. Unfortunately the facts observed up to this time do not confirm this theoretical view. Since I established at Morges a self-registering limnimeter of the greatest sensitiveness, in March, 1876, six different earthquakes have been noticed in our country, and specially three earthquakes were felt at Morges itself—May 7 and November 29, 1876, and October 8, 1877. Not one of those six earthquakes has been traced by the self-registering limnimeter; not one has interrupted the rhythmic oscillation of the *seiches* which were taking place; not the smallest alteration of the curve has shown that the water had been acted upon in a peculiar manner; neither was the limnimeter of M. Ph. Plantamour, which was at work during the earthquake of October 8, 1877, influenced by that very severe shock. And yet our apparatus are extremely sensitive; when the lake is sufficiently calm my limnimeter can show the waves originated by a steamboat which passes 10 15 kilometres off the apparatus, or it registers the waves caused by a steamer which has passed by my observatory two or three hours before.

How can these contradictory facts be explained? On one hand, the earthquakes cause in many places enormous waves; on the other, three earthquakes strong enough to have awakened men out of their sleep, have not put in movement the most sensitive, always working, self-registering apparatus.

I suppose that the shocks of the earth do not transfer always the movement to the water; that only in a special direction of the shock a special intensity, a special duration, the water itself is put in movement and takes the rhythmic oscillation of the *seiches*. If I shake a basin the water is not always and necessarily put in oscillatory movement. I think it is the same for the *seiches*, and I believe that only certain movements of the earth cause the water of the lakes to move.

It is the point on which I seek an answer from naturalists who have more opportunity to observe the effects of earthquakes. I ask if each earthquake is accompanied by waves of the sea; if each shock of the same intensity is accompanied by waves of the same amplitude; if there are not differences between the different earthquakes; if some have the enormous waves of Iquique or Arica; if others are without those waves?

I should be very thankful to receive an answer to the above questions. F. A. FOREL

Morges, Switzerland, January 24

Electrical Experiment

A FRIEND of mine has called my attention to a letter of F. T. Pirani, of Melbourne, accompanied by some remarks of Prof. J. C. Maxwell, in NATURE, vol. xvii. p. 180.

Mr. Pirani concludes his letter with the words, "If the phenomenon (described in the letter) has not been noticed before, I shall be obliged to you if you will kindly communicate it to NATURE."

I take the liberty to request you to call, by means of your esteemed journal, the attention of the author to an article of mine, published in the late Prof. Poggendorff's *Annalen der Physik* (vol. clvii., 1876), an abstract of which appeared in the *Philosophical Magazine* (5 ser. vol. i.). The phenomenon alluded to in Mr. Pirani's letter, *i.e.* the existence of an electromotive force due to gravity, in a vertical column of an electrolyte, is, I believe, fully proved by the experiments described in the article. The same difficulties met with by Mr. Pirani and Prof. Maxwell, who repeated the experiment, that is, the presence of irregular, casual currents, due to bubbles of air, &c., have also been encountered by me; I intimate the means of getting rid, to a certain extent, of this influence.

The transport of metal in one direction being accompanied by a transport of the other ion in the opposite direction, the phenomenon is more complete than it might appear at first sight, and the electromotive force changes its sign according to the electrolyte employed.

Kasan, Russia, January 23

Oriental Affinities in the Ethiopian Insect-Fauna

MANY naturalists have already drawn attention to the Indian affinities in the African fauna; in other words, the zoological relationship between the Oriental and Ethiopian regions. The late Dr. Stoliczka has pointed this out in the Malayan ornithology; Mr. Wallace has described the same thing in the mammalia and birds of West Africa, these possessing "a special Oriental or even Malayan element." He has also drawn attention to the Oriental element in the Ethiopian reptiles and amphibia, and to the many cases of the same in the South African fauna. Mr. Blandford has treated of the "African element in the fauna of India," more particularly as regards the mammalia; and the late Mr. Blyth has shown the ancient date of this relationship from the evidence afforded by the Siwalik deposits. Mr. Murray has even inclined to the opinion that the Indo-Malayan region should be included with that of Africa, south of the Sahara.

The "Insecta" of the Ethiopian region also shows the same Oriental relationship, which seems to have hitherto received less attention. Dr. Stoliczka has described this in the "Indian Arachnoidea," and Mr. A. Murray in the coleoptera of which he has given the names of eleven genera common to the two regions.

The same thing may be seen in the Lepidoptera and Hemiptera, of which I can only treat briefly, hoping to deal with the subject in a more exhaustive and analytical form when possessed of adequate data, which at present do not exist.

Of the Lepidoptera a few specific examples will perhaps serve the purpose better than the names of the many genera that could be adduced. In the Rhopalocera:—*Danaus chrysippus*, *Melanitis leda*, *Atella phalanta*, *Hypanis ilithyia*, *Lycæna telicanus*, *Idmais phisadia*, and *Callosune danae*, all belong to the two regions, and with the exception of *C. danae* and *I. phisadia*, have been all recorded from Madagascar. However, *D. chrysippus* (Greece and Turkey), *H. ilithyia* (Nubia, Abyssinia, and Arabia), and *L. telicanus* (Egypt and Arabia), would seem to show from those habitats their route of migration from one region to the other. In the Heterocera two examples must suffice, and may be accepted as typical of what probably occurs to a far greater extent among the large number of African moths still unknown to science. *Plusia verticillata* and *Patula macrops* have a wide range over the two areas.

In the African Hemiptera-Heteroptera the Oriental relationship is very pronounced. The following are some of the genera common to the two regions:—*Solenosthedium*, *Hotea*, *Coptosoma*, *Brachyplatys*, *Plataspis*, *Canthecona*, *Agonoscelis*, *Antestia*, *Bathycælia*, *Catacanthus*, *Tesseratoma*, *Aspongopus*, *Phyllocephala*, *Macrina*, *Mictis*, *Leptoglossus*, *Odontopus*, *Physopelta*, *Lestomerus*, *Catamiarus*, *Pachynomus*, *Acanthaspis*, *Oncocephalus*, and *Thodelmus*. Genera, of course, are subject to constant revision and redivision, making, as a rule, generic calculations of geographical distribution very uncertain and unstable. A genus of to-day may embrace species belonging to two regions; to-morrow an author may split this genus into two, for which he may find local characters. In other words, genera common to two regions at the present time may be shown as the contrary by a later worker. In a general way the value of the term genus is often equal to the value of the term species. The twenty-four genera of Hemiptera, however, which I have enumerated above, may be accepted as more certain examples. Dr. Stål has paid particular attention to this order, and has made many genera from a minute examination of structure, and I think his divisions must at least be considered as sufficiently exhaustive. I have carefully compared my list with his latest classification, and find that eighteen out of the twenty-four genera still remain intact on his catalogue, one other is common to the two regions from an East African species I recently described, and so only five remain, which Dr. Stal has further subdivided. Of these twenty-four genera, *twenty-two extend to the West African sub-region*, twelve have at the present time also been recorded from China, and twelve from the Australian region. When we further analyse the list as to the probable route of migration, it is found that eight genera appear in Madagascar and two in Réunion; whilst a northern junction is also indicated by one genus being found in Tangier and Syria, two in Egypt, and one in Abyssinia. A few species are common to the two regions, as *Leptoglossus membranaceus*, *Oncocephalus annulipes*, &c.

It is probable that the African Neuroptera and Orthoptera may show the same affinities.

Sense in Insects—Drowned by a Devil-Fish

In the file of NATURE from October 18 to the end of November which I have just received, I find a discussion regarding the senses possessed by insects, especially the lepidoptera. For years I have been in the habit of collecting these insects for my friends, and of course have become more or less acquainted with their habits. I recall one or two instances in point. In Costa Rica the Heliconias frequent certain flowers, and pass over others of the same colour and same approximate size without noticing them. But the most marked case was of the large brilliant Morphos. My Indian servants always carried with them a fermented paste of maize flour, which they mixed with water to the consistency of gruel as a beverage. On our arriving at the side of a stream in a narrow gorge, invariably, within a few minutes after they opened a package of this paste, although there might not have been a butterfly in sight before, those most brilliant of their kind would come sailing up, always from leeward, and I have made some of my best catches in this manner. I have also caught them by baiting with a piece of over-ripe or even rotting banana. At other times they were almost unapproachable. They seem to live on fruits just merging into the state of rottenness.

I have never been able to detect any sensitiveness to sound in insects, and suspect that the case cited by one of your correspondents might be equally explained by sight, or by the vibration of the air caused by striking the glass. That certain coleoptera and diptera are attracted by smell alone is too obvious to require proof.

The same may be said of ants in following an established trail. I have experimented with this frequently, obliterating the scent for a space of but a few inches; and watching the puzzled wanderers each going an inch or less beyond his predecessor, hunting the lost clue until the blank was finally bridged over. After that if the new route as re-opened differed from the old, it was nevertheless rigidly followed even if longer and less direct.

Another matter. You mention a case of "drowning by a devil-fish" (NATURE, vol. xvii. p. 27). The story is to me very probable. I once measured a specimen of my *Octopus punctatus* caught in San Francisco harbour, which gave clear 15 feet from point to point of the arms. The animal, as I bought it from a fisherman, filled a champagne basket.

W. M. GABB

Puerto Plata, Sto. Domingo, December 29, 1877

Drowned by a Devil Fish

THOUGH in British Columbia at the time of the occurrence of the incident referred to by Mr. Moseley in NATURE (vol. xvii. p. 27) I was in the interior, and consequently heard nothing of the [illegible]ter. On reading Mr. Moseley's letter, however, I wrote to my friend Dr. W. F. Tolmie, of Victoria, and have just received from him an account verifying in all essential particulars the extract quoted by Mr. Moseley from the *Weekly Oregonian*.

A party of Makaw or Makah Indians of Cape Flattery were returning from a visit to the Songish Indians of the vicinity of Victoria, and camped the first afternoon at Metchosin, on the south shore of Vancouver Island. A young woman having separated herself from the others to bathe, did not return in the evening, and after having searched for her in vain the next morning, the rest of the party were about to continue on their journey, when, on rounding the first point, they saw the body of the woman as if seated on the sandy sea-bottom, with a large octopus attached to it, which, according to the description of Dr. Tolmie's informant, resembled a "fifty-pound flour sack, full." The body was rescued in the manner described in the *Oregonian*, and when brought ashore, still had portions of the arms of the octopus adhering to it.

Dr. Tolmie also mentions the case of an Indian woman at Fort Simpson, who had, many years ago, a narrow escape from a similar death; also that among the Chimsyan Indians traditions of escapes and occasional cases of drowning exist, and further, that among these people a story is current that "A two-masted vessel manned in part or whole by men with obliquely placed eyes and wearing queues (at Milbank Sound, lat. 52°, about seventy years ago) was seized by an enormous squid, whose tentacles had to be chopped with axes ere the craft was clear of it. The ship is said to have been wrecked further south on the coast, in consequence of the evil influence of the monster."

GEORGE M. DAWSON

Geological Survey of Canada, Montreal, January 11

Eucalyptus

IN NATURE, vol. xvii. p. 10, Mr. A. Nicols says he has seen attacks of fever come on in a forest of Eucalyptus; malaria prevails there, he maintains. Does that malaria, the degree of gravity of which he does not describe, seriously compromise health? That is the question. It is probable, notwithstanding the presence of Eucalyptus, that there are yet numerous cases of fever near Lake Fetzara (Algeria), but really of such small importance as to permit, without serious danger to health, the working of the ground or the mines of these districts.

As to mosquitoes, allow me to recall that there exist very many species of these animals which, apart from their common quality of feeding on and tormenting mammals, and especially man, have origins, habitats, evolutions and habits completely different; some live only in the larval state, others frequent moist ground, and other live, always in the larval state, in fungi In a country which is far from being tropical and marshy, Newfoundland, the pine woods are infested during the short summer by myriads of mosquitoes, which become a real danger for the rash traveller. It will be understood that all these species do not exist at the same time in the same place, and that at Lake Fetzara the marshes are being profoundly modified, or are disappearing, and the mosquitoes, properly called, are also disappearing. Moreover, if there does not exist in the country, as is probable, any species of mosquito living in the shade of the forest, the country will be rid of these animals, a thing which cannot take place in Australia, where there are species living in the forests. In other words, it is not the Eucalyptus which at Fetzara has caused the mosquitoes to disappear, but rather the absence of the conditions necessary to the life and reproduction of mosquitoes, which have become deficient in consequence of the modification of the soil, brought about by the numerous plantations of Eucalyptus.

DR. CALMY

Saigon, December 10, 1877

Explosive Dust

IN NATURE, vol. xvii. p. 123, I noticed a letter by A. Mackennah on an explosion of malt dust in a grinding machine. This I believe to be not an uncommon occurrence, as I hear there have been three explosions in our mill within a period of four years, and these not due to any such culpable carelessness as allowing a naked flame to approach the heated impalpable dust, but ignited either by a spark from a piece of flint passing through the steel rollers (barley from some localities is invariably accompanied by quantities of small fragments of flint), or from excessive friction on some part of the wood fittings.

The following facts I obtained from the man in charge of our mill at the time of the worst of these explosions, about three years ago:—

They were grinding at the ordinary pace about mid-day with the window open and no gas turned on.

The explosion was quite sudden and the flame sufficient to singe the man's whiskers; the force was so great that the door of the engine-room was blown open, though the only opening between the two rooms was a small hole through which the shafting worked.

Having had several holes bored through the wood lining to allow a free current of air, there has been no explosion since.

The danger of fine impalpable coal dust in collieries is too manifest to need argument based on the action of analogous bodies, but still the above facts may interest some of your readers.

Burton-on-Trent, January 22

Dendritic Gold

WILL one of my fellow-readers of NATURE be good enough to inform me, through its columns, with the name and publisher of such a work on mineralogy (short, if possible) as will give me the best information on the subject of the dendritic gold existing in sandstones in New Zealand, as reported in the *Proceedings* of the Wellington Society (NATURE, vol. xvi. p. 507).

It is my wish specially to know the colour of such dendrites, the geologic age of the rock containing them, and, if possible, to obtain a satisfactory account of their origin, as hitherto I have believed that metals take this form solely by deposition from solution.

I ask this in the interest of friends in South Africa (in addition to the personal desire for knowledge), where, in many parts of the Transvaal, gold "prospects" can be obtained, though usually in quantities unprofitably small, in nearly every case there being no quartz from which it could have been derived; at least so said my informants, old Australians.

Black dendrites I have noticed between the (once) horizontal strata of sandstone boulders in the Kimberley diamond mine, but was unable, at the time, to decide their nature.

R.

DEMONSTRATION OF CURRENTS ORIGINATED BY THE VOICE IN BELL'S TELEPHONE

IF two wires, A and B, be respectively connected with the two binding screws, R and S, of a telephone, and the other ends of the wires be connected with a Thompson's reflecting galvanometer, the following experiments can be made:—

1. On pressing in the iron disc a deflection is produced on the scale, say, from right to left.

2. On reversing the wires so that A is connected with S and B with R, and repeating Experiment 1, a deflection is produced in the opposite direction, *i.e.* from left to right.

3. Shouting or singing produces no deflection.

If a Lippmann's capillary electrometer be substituted for the galvanometer, the following results are obtained:—

4. If Experiments 1 and 2 be repeated, similar movements are observed, *i.e.* in one case the mercury column moves to the point of the capillary tube, in the other away from it.

5. If the gamut be loudly sung up, note by note, to the sound *ah*, one note is found to give a movement of the mercury column, about ten times as great as that observed in Experiment 4, towards the point of the tube. The octaves, especially the higher ones, and some harmonics of this note yield similar results. (It is this note which tetanises a nerve muscle preparation as observed by Fick, &c.)

6. If the wires be reversed and the same note sung, a movement of the mercury column is seen as large as that in Experiment 5, but in the *same* direction. *So that reversing the wires does not alter the direction as indicated by the electrometer.*

7. If the primary wire of a Du Bois Reymond's coil be placed in the circuit of a telephone, and the wires from the secondary circuit coupled with the electrometer, the note mentioned above produces the same movement as in Experiments 5 and 6, when the secondary coil is about

8 cm. from the primary. *Reverse the wires in the secondary circuit, reverse the wires in the primary circuit, how you please, the mercury always moves towards the point of the capillary.*

8. Shouting or singing (excepting the above-mentioned note) produces no visible effect under the conditions mentioned in Experiments 5, 6, and 7.

9. If the secondary coil be now moved close up, so as to cover as completely as possible the primary, talking to the telephone with the ordinary voice, *i.e.* with moderate strength and at any pitch, produces a definite movement of the mercury column for each word, some sounds of course giving more movement than others, *but the movement is always towards the end of the capillary.* Singing the note mentioned in Experiments 5, 6, and 7 loudly, produces a movement too large to be measured with the electrometer.

Reversing the poles of the magnet in the telephone does not alter the results of Experiments 5, 6, 7, and 9.

On mentioning the above results to Dr. Burdon Sanderson, he suggested that the apparently anomalous behaviour of the electrometer might be accounted for, by supposing that the mercury moved *quicker* when a current passed towards the point of the capillary than when it flowed in the opposite direction; so that if a succession of rapidly alternating currents be passed through the instrument, the mercury will always move towards the point of the capillary, the movement away from the point being masked by the sluggishness of the instrument in that direction. That this explanation is the correct one is proved by the following experiment:—The current from two Grove's cells is sent through a metal reed vibrating 100 times a second, the contact being made and broken at each vibration, the primary wire of a Du Bois Reymond's induction-coil is also included in the circuit; on connecting the electrometer with the secondary coil placed at an appropriate distance the mercury always moves to the point of the tube whatever be the direction of the current.

F. J. M. PAGE

Physiological Laboratory, University College,
London, February 2

NOTE.—On February 4 Prof. Graham Bell kindly placed at my disposal a telephone much more powerful than any of those I had previously used. On speaking to this instrument, the electrometer being in the circuit, movements of the mercury column as considerable as those in Experiment 9 were observed.—F. J. M. P.

CHEMISTRY AND ALGEBRA

IT may not be wholly without interest to some of the readers of NATURE to be made acquainted with an analogy that has recently forcibly impressed me between branches of human knowledge apparently so dissimilar as modern chemistry and modern algebra. I have found it of great utility in explaining to non-mathematicians the nature of the investigations which algebraists are at present busily at work upon to make out the so-called *Grundformen* or irreducible forms appurtenant to binary quantics taken singly or in systems, and I have also found that it may be used as an instrument of investigation in purely algebraical inquiries. So much is this the case that I hardly ever take up Dr. Frankland's exceedingly valuable "Notes for Chemical Students," which are drawn up exclusively on the basis of Kekulé's exquisite conception of *valence*, without deriving suggestions for new researches in the theory of algebraical forms. I will confine myself to a statement of the grounds of the analogy, referring those who may feel an interest in the subject and are desirous for further information about it to a memoir which I have written upon it for the new *American Journal of Pure and Applied Mathematics*, the first number of which will appear early in February.

The analogy is between atoms and *binary* quantics exclusively.

I compare every binary quantic with a chemical atom. The number of factors (or rays, as they may be regarded by an obvious geometrical interpretation) in a binary quantic is the analogue of the number of *bonds*, or the *valence*, as it is termed, of a chemical atom.

Thus a linear form may be regarded as a monad atom, a quadratic form as a duad, a cubic form as a triad, and so on.

An invariant of a system of binary quantics of various degrees is the analogue of a chemical substance composed of atoms of corresponding *valences.* The order of such invariant in each set of coefficients is the same as the number of atoms of the corresponding *valence* in the chemical compound.

A co-variant is the analogue of an (organic or inorganic) compound radical. The orders in the several sets of coefficients corresponding, as for invariants, to the respective valences of the atoms, the free valence of the compound radical then becomes identical with the degree of the co-variant in the variables.

The weight of an invariant is identical with the number of the bonds in the chemicograph of the analogous chemical substance, and the weight of the leading term (or basic differentiant) of a co-variant is the same as the number of bonds in the chemicograph of the analogous compound radical. Every invariant and covariant thus becomes expressible by a *graph* precisely identical with a Kekuléan diagram or chemicograph. But not every chemicograph is an algebraical one. I show that by an application of the algebraical law of reciprocity every algebraical graph of a given invariant will represent the constitution in terms of the roots of a quantic of a type reciprocal to that of the given invariant of an invariant belonging to that reciprocal type. I give a rule for the geometrical multiplication of graphs, *i.e.* for constructing a *graph* to the product of in- or co variants whose separate graphs are given. I have also ventured upon a hypothesis which, whilst in nowise interfering with existing chemicographical constructions, accounts for the seeming anomaly of the isolated existence as "monad molecules" of mercury, zinc, and arsenic—and gives a rational explanation of the "mutual saturation of bonds."

I have thus been led to see more clearly than ever I did before the existence of a common ground to the new mechanism, the new chemistry, and the new algebra. Underlying all these is the theory of pure colligation, which applies undistinguishably to the three great theories, all initiated within the last third of a century or thereabouts by Eisenstein, Kekulé, and Peaucellier.

Baltimore, January 1 J. J. SYLVESTER

PALMEN ON THE MORPHOLOGY OF THE TRACHEAL SYSTEM

DR. PALMEN, of Helsingfors, has recently published an interesting memoir on the tracheal system of insects. He observes that although the gills of certain aquatic larvæ are attached to the skin very near to the points at which the spiracles open in the mature insects, and though spiracles and gills do not co-exist in the same segment, yet the point of attachment of the gills never exactly coincides with the position of the future spiracle. Moreover, he shows that even during the larval condition, although the spiracles are not open, the structure of the stigmatic duct is present, and indeed that it opens temporarily at each moult, to permit the inner tracheal membrane to be cast, after which it closes again. In fact, then, he urges, the gills and spiracles do not correspond exactly, either in number or in position, and there can therefore be between them no genetic connection. He concludes that the insects with open tracheæ are not derived from ancestors provided with gills, but, on the contrary, that the possession of a closed tracheal system is a secondary condition, derived from ancestors provided with spiracles.

He adopts the view that the existing insects are derived from an ancestor, in which the larvæ resembled the existing genus Campodea, with a hemimetabalous metamorphosis, and an open tracheal system; and he dwells on the important fact that in Campodea each spiracle has an independent set of tracheæ. So also in the course of embryonal development, the tracheal systems rise separately, and then the anterior and posterior branches unite to form the lateral ducts.

In a still earlier stage he thinks it probable that the tracheæ resembled those of the curious genus Peripatus. He observes that the skin-glands of certain worms secrete not only fluid, but also gas (carbonic acid), and from this to an absorbing function would be a comparatively small step. He supposes, then, that the tracheæ are derived from the skin-glands of worms, passing firstly through the stage now represented by Peripatus, in which there are a number of tracheal tubes with numerous scattered openings; secondly, though one represented now by Campodea and certain myriapods, in which the spiracles are situated in pairs, and are connected with separate tracheal systems.

I. L.

ON THE EVOLUTION OF HEAT DURING MUSCULAR ACTION[1]

PROF. A. FICK, of Würzburg, in continuing his researches on the source of muscular power, has obtained some new and exceedingly important results, of which the following is a condensed account:—

It is obviously an interesting question in the physiology of muscle what fraction of the work yielded by chemical action in muscular tissue can be employed in overcoming mechanical resistance? the remainder of the chemical work appearing, in all probability, as heat.

Many years ago Helmholtz calculated, from certain considerations, into which, however, there entered several hypothetical factors, that possibly one-fifth of the total work yielded by chemical force in the human body might be employed in muscular action, the remaining four-fifths appearing as sensible heat. From this it necessarily follows that a much larger proportion than one-fifth of the work yielded by chemical force *in the muscle itself* can be employed in overcoming mechanical resistance, inasmuch as it is assumed that a great part of the oxidation takes place in other tissues, where mechanical work is quite out of the question, and where heat alone can be the result.

If, however, thermodynamical experiments show that of the chemical work going on in the muscle only a small fraction, not much exceeding one-fifth, produces mechanical effect; then, supposing the coefficient of Helmholtz to be true, it would be proved that only minute quantities of combustible material are oxidised elsewhere than in the muscles. The author's experiments have been made with a view to answer the first of the above questions—what fraction of the chemical force eliminated in the muscle is used in mechanical work? Such experiments can, of course, with the present means of research, only be carried out upon the muscles of the frog. How far the results obtained are applicable to other classes of animals, is a distinct question.

Thus two magnitudes have to be determined in absolute measure, viz., the mechanical work performed by the muscle, and secondly, the amount of chemical work that the muscle has yielded during the action.

The amount of heat produced in the muscle was of course measured by multiplying the rise in temperature of the muscle by its capacity for heat. In the calculations the specific heat of muscle was taken as equal to that of water. It cannot be greater, and is probably not much less, inasmuch as three-fourths of living muscle are water. The rise in temperature was measured by thermo-electrical means. The galvanometer used had no fixed magnet, and its constancy was proved to extend over many weeks, and even months. The thermopile had to be so arranged that it was as much as possible surrounded by the mass of muscle; its construction will be better understood after the preparation has been described. The gastrocnemius muscle, which is the favourite preparation in such experiments, was replaced by the masses of muscle which pass from the pelvis to the tibia on the inner side of each thigh, whilst the other muscles, with the sartorius and biceps, as well as both the thigh-bones, were removed. Then, on suspending the pelvis, the two prepared masses of muscle hung vertically downwards in intimate contact with each other, all the nerves belonging thereto being easily preserved. One end of the thermopile, with very flat and thin elements, was then placed in the fissure between the two masses of muscle, this arrangement being found by experience to be a perfectly trustworthy one.

A remark is necessary concerning the method of irritating the preparation. Some years ago the author had the opportunity of observing, in some unpublished experiments, that an electric current of sufficient strength to produce the most powerful contraction in a muscle, does not appreciably raise the temperature of the latter. Even with Heidenhain's exceedingly delicate thermopile there was scarcely any evidence of heat being produced in a dead muscle through which a current of twenty-four Daniell's elements was passing for several seconds; and even induction currents of immense strength produced no visible thermal effect. This fact is of great interest in myothermic experiments, as it is thus no longer necessary to impart the stimulus through the nerve, but simply to subject the muscle to direct electrical irritation.

In his experiments, the author has adopted preferentially the method of direct irritation, one of the two copper wires connected with the induction-coil being attached to the pelvis, and the other to the knee of the frog.

The mechanical work was measured by connecting the preparation with one arm of a lever to which a weight was attached, and, in some of the experiments, there were also two balanced weights placed upon the lever to increase its inertia, by which it was found that the work performed was very considerably increased.

The following is a summary of the chief results arrived at by these experiments:—

1. By the interposition of a thin thermopile between suitable masses of muscle, it is possible to determine with great accuracy the absolute amount of heat produced by their contraction.

2. The determination of the muscle-temperature is not interfered with by electrical currents, which, for the purpose of irritation, are passed through the muscle. Therefore direct electrical irritation of the muscle is permissible, and indeed far preferable, in myothermic researches.

3. To the fundamental law of Heidenhain, that a muscle contracting to its greatest extent evolves more heat the greater its initial tension, we may now add that, with equal initial tension, a muscle will evolve more heat if, by means of weights in equilibrium, greater tension be produced during the contraction.

4. A muscle overcoming a greater resistance, works not only with more activity but also with more economy than when occupied in a smaller effort.

5. In an energetic muscular contraction against as great a resistance as possible the eliminated chemical force is about four times as great as the mechanical work it performs. With a less resistance the chemical is a greater multiple of the mechanical force, and with no resistance at all it is obviously indefinitely greater.

6. The amount of heat produced by the eliminated chemical force in an energetic contraction of 1 grm. of

---

[1] "Ueber die Wärmeentwickelung bei der Muskelzuckung," in the *Archiv. f. Physiologie*, Band xvi.

untired frog's muscle is sufficient to raise 3 mgrm. of water from 0° to 1° C.

7. By adopting some very probable assumptions it can be inferred that the combustion of assimilated food, as far as the oxygen inspired is employed in producing chemical force, takes place almost exclusively in the muscular tissues.

P. FRANKLAND

ERNST HEINRICH WEBER

WE are called upon to chronicle the death, at Leipzig, on January 26, of Prof. Ernst Heinrich Weber, whose name is so closely united with the fundamental principles of modern optics and acoustics. He was born at Wittenberg, June 24, 1795, and after having studied at the university of that city received, in 1815, the degree of M.D. Two years later he published a short work on the anatomy of the sympathetic nerves, which brought his name at once into prominence. The following year he was appointed extraordinary professor of anatomy at the University of Leipzig, and in 1821 he became ordinary professor of human anatomy. He was early well known by his edition of Hildebrandt's "Anatomie," of which he wrote anew a considerable part in 1830. The chair of physiology was offered to him in 1840, and he actively fulfilled the duties of this position until a short time before his death. During this period he issued several manuals of physiology, and published a number of investigations, the most valuable of which are gathered together in his book "Annotationes anatomicæ et physiologicæ" (1851). Science is, however, chiefly indebted to Prof. Weber for the classical researches carried out by him and his brother Wilhelm Eduard while still young men, on which is grounded the celebrated wave-theory. The work in which their investigations are recorded—"Die Wellenlehre auf Experimente gegründet" (1825), is a remarkable relation of the most delicate and ingenious observations ever undertaken to establish a series of physical laws. Among the most notable of these might be mentioned the experiments on waves of water in mirrored troughs, by means of which they found that the particles near the surface move in circular paths, while those deeper in the liquid describe ellipses, the horizontal axes of which are longer than the vertical. By another series of comparative observations on water and mercury the law was established that waves moved with equal rapidity on the surfaces of different mediums, while the rapidity increases in both cases with the depth of the liquid. These and a multitude of other facts, studied and elaborated in the most scrupulous and conscientious manner, form the basis for the whole theoretical structure accepted at present as explanatory of the phenomena of light and sound. So thoroughly and scientifically were these researches carried out that subsequent physicists have never been called upon to correct them. In 1850 Prof. Weber completed an extensive series of experiments designed to study the wave-movement in the arterial system and explain the fact that the pulse-beat was felt at the chin a fraction of a second sooner than in the foot. The results showed that the pulse-beat travels with a rapidity of about thirty-five feet per second, and that in general the rapidity of a wave in small elastic tubes is not affected by the increase of pressure on the walls. At a later date Prof. Weber published some interesting results of experiments on the mechanism of the ear, as well as on the microscopic phenomena visible on bringing together alcohol and resin suspended in water in capillary spaces.

DR. P. BLEEKER

ON January 24 death quite suddenly overtook one of the most indefatigable workers in the field of zoological science, the well-known ichthyologist, Dr. P. Bleeker, who died at his residence in the Hague, at the age of fifty-nine. Born at Zaandam in 1819, he had an early taste for natural history, and studied medicine with a view to an appointment in the army. In 1838 he received an appointment in the medical staff of the East Indian army, and left for Batavia. Here an immense field was soon opened to his activity. He set himself to form an immense collection of fishes from different parts of the colonies, assisted in many ways by a number of his medical colleagues at different stations. He himself always remained at Batavia, gradually rising in his profession till he obtained the inspectorate of the Colonial Medical Service. At the same time he was the centre of a keen scientific movement in the capital of the Dutch Indies, starting several societies and taking the chair in the principal of them for many consecutive years. His contributions to the Indian ichthyological fauna were regularly published in Batavian scientific journals. In 1860 he returned to his native country, and first took up his residence at Leyden, with a view to comparing the treasures contained in the zoological collections there with his own. Extensive consignments of fishes had been made by him to this institution at the time of his residence in Batavia, part of the arrangement and determination of which he now took upon himself. Not long afterwards he went to live at the Hague, where the dignity of Councillor of State Extraordinary was conferred upon him. He set to work at the gigantic task he had undertaken—the publication of his "Atlas Ichthyologique des Indes Orientales Néerlandaises," seven volumes of which, illustrated by several hundreds of coloured plates have appeared. He was herein largely assisted by grants from the Colonial Government. Many important groups, the Gobioidæ, the Scombridæ, the Scorpænidæ, &c., as well as the whole of the Elasmobranchs are left unfinished. He himself estimated that little less than half of the work remained to be published, and latterly had misgivings whether he would really be able to finish it.

The number of separate publications on East Indian fishes which have appeared from his hand in different journals exceed three hundred; they form the basis on which he gradually raised the structure of his Atlas.

He had brought home his large collection of spirit specimens which has always remained in his private possession. Of late years, as he advanced with the publication of his Atlas, he disposed of the specimens of those groups which he had finished; in this way no less than 150 of his unique type-specimens were acquired by purchase by the British Museum. Another disadvantage under which a private collection of these dimensions often labours—and Bleeker's was no exception—is the loss of the exact localities from which the different specimens of one species were procured, a detail which is afterwards of such high importance in determining the geographical range of varieties. Here, however all the specimens are mixed together in one bottle without being separately labelled.

An extensive collection of reptiles and amphibians from the Archipelago, on which he had published several papers during his stay in India, have passed to the British and Hamburg Museums.

ABOUT FISHES' TAILS

MOST people know the difference in shape that there is between the tail (caudal fin) of a salmon and that of a shark; how in the former the lobes of the fin seem to be equal or symmetrical (homocercal), and in the latter only the lower lobe of the fin is, as it were, developed, and the back bone (vertebræ) of the fish seems to be prolonged into the feebly-developed upper lobe (heterocercal). This remarkable distinction was first of all recognised by Agassiz, and long ago Owen wrote, "the preponderance of heterocercal fishes in the seas of the geological epochs of our planet is very remarkable; the prolongation of the superior lobe characterises every fossil fish of the strata anterior to and including the magnesian limestone; the homocercal fishes first appear above that formation and gradually predominate until, as in the present period, the heterocercal bony fishes are almost limited to a single ganoid genus (Lepidosteus)." "Indeed," writes Prof. Owen in another place, "it [the heterocercal] was the

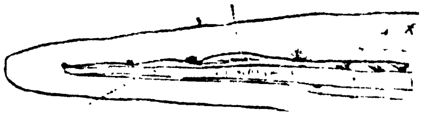

Fig.

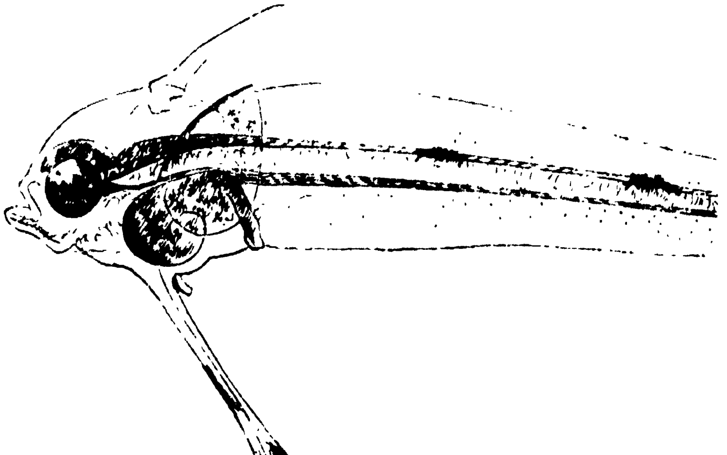
fashion of tail which prevailed in fishes throughout the palæozoic and triassic periods." It never seems to have been settled whether the fish with the homocercal tail was or was not better off than the fish with the heterocercal tail. If the more recent fishes have improved in this matter of tails upon the more ancient fishes, as was to have been

expected, certain it is that the shark of to-day can wheel quickly enough about in pursuit of his prey, and that the sword-fish can come thundering against a ship's timber with a vigour not easily matched by any fish with a symmetrical tail. Be this, however, as it may, the structure of fishes' tails has engaged the attention of most of our comparative anatomists, and the student will find large stores of facts collected and arranged for him by Agassiz, Vogt, Owen, Kölliker, Hæckel, Huxley, and Lotz. The latter four anatomists have plainly shown that while the external appearance of the tail of modern bony fishes is, as we have seen, homocercal, their real structure is only a modified heterocercal one, so that, as far as we now know, the tail of all fishes is built upon modifications of the same type, and in a paper just published by Alexander Agassiz, "On the Young Stages of some Osseous Fishes," he proves still further that this tail fin does not differ in its mode of development from the primitive embryonic fin, or from that of the back (dorsal) fin. He describes the gradual change of the

Fig.

embryonic tail in several species of bony fishes, and he calls attention to the remarkable presence of an embryonic caudal lobe, which has, to this, apparently escaped the attention of naturalists, and which shows remarkably well the identity of growth between the tails of ganoid and of bony fish.

Alexander Agassiz traces the changes gradually taking place in the tail of the common flounder, from the time the little fish leaves the egg until it has nearly assumed the final shape of the adult. At first (Fig. 1) the caudal end of the chorda is straight. The caudal fin is rounded. In the next the caudal extremity of the chorda has become slightly bent upwards, and there will be found the first



trace of the division line between the embryonic and the permanent caudal fins. In further stages this indentation between these two becomes more marked the chord becomes more arched, and the permanent caudal at length projects well beyond the outline of the embryonic fin fold, so that antecedent to the ossification of any of the vertebral column, the tail has assumed a heterocercal form.

In the stage (Fig. 2) in which the embryonic caudal assumes the shape of a large independent lobe, while the permanent fin appears like a second anal fin, the resemblance to the tail of a young Lepidosteus is most striking. The extremity of the notochord at last disappears preparatory to the formation of the urostyle, while the permanent caudal gradually develops, and soon it (Fig. 3) presents the general outline of the adult form.

A. Agassiz has traced the presence of this remarkable embryonic caudal-lobe in a large number of genera of bony fish. In the young of Syngnathus it is well marked. In the young of the fishing-frog (Fig. 4) (*Lophius*) the termination of the notochord remains unchanged quite late in life, but in all the genera examined the permanent tail passes quite gradually from a strictly ventral appendage placed below the dorsal column to that of a terminal tail placed in the continuation of the vertebral column.

A. Agassiz thinks that though Agassiz and Vogt were mistaken as to their details, their great generalisation will still remain true, and that there is a complete accordance between the embryonic growth of fishes' tails and the development of fishes in time, only we must now remember that the heterocercal tail is *not* the earliest stage—that the earliest stage is a nearly symmetrical one; this which he calls the leptocardial stage is that assumed by the tails of bony as well as of all other fishes, and *precedes* the heterocercal stage. As to the palæontological record, if one examines the tails of the Devonian fish as we know them from the restorations of Agassiz, Hugh Miller, Hæckel, Huxley, and others, one is quite struck by the perfect parallelism of these ancient fishes, as far as the structure of their tail is concerned, with the structure of the stages of the flounder's tail already referred to, thus carrying out the parallelism of Agassiz and Vogt far beyond anything they even conjectured. This important paper of A. Agassiz was presented to the American Academy of Arts and Sciences in October last, and for an early copy of it we are indebted to the author.

E. PERCEVAL WRIGHT

OUR ASTRONOMICAL COLUMN

Literature of the Nebulæ and Clusters.—No. 311 of the *Smithsonian Miscellaneous Collections* is just received. It contains an "Index Catalogue of Books and Memoirs relating to the Nebulæ and Clusters, &c.," by Prof. Holden, of Washington, commenced in 1874 for his own use, and now published in the hope, as he states, that it may be found as useful to others as it has already been to himself. It is believed to be nearly complete so far as the uses of the astronomer can require, but it has not been Prof. Holden's object to make an index for the bibliographer. The present catalogue affords facilities in the several cases that are most likely to arise, as first, in the event of all that is published on nebulæ and clusters in a particular series—the *Philosophical Transactions*, for instance—being required; again, where all papers upon the subject by any one author are sought for, and further, when all papers written upon any special subject, no matter by what author, are in question. A very useful indication of the contents of a large number of the memoirs and notices forms a feature in the work, Sir W. Herschel's papers being noticed in abstract with particular fulness. The great nebula in Orion and the variable nebulæ claim separate sections. There are also lists of figured nebulæ and an index to Sir W. Herschel's Catalogues adopting the identifications of his son's General Catalogue.

Prof. Holden has rendered an essential service to all who may be occupied with this interesting branch of astronomy, who will find his index of the greatest assistance in enabling them to learn, at the expense comparatively of little time and trouble, all that has been written upon many special subjects and upon the nebulæ and clusters generally.

New Southern Variable Star.—Mr. Tebbutt—who, it will be remembered, was the discoverer of the great comet of 1861 while yet telescopic—writing from Windsor, New South Wales, on November 23, notifies his having detected what would appear to be a remarkable variable star in the constellation Ara. He had seen it as a star of the fifth magnitude while observing Comet III., 1862, between October 3 and 9; it was then brighter than σ Aræ, and plainly visible to the naked eye. Its place was fixed by sextant-distances from four stars. At the time of writing, Mr. Tebbutt mentions that the only star in the observed position was one of the eleventh magnitude, barely distinguishable in moonlight in his 4½-inch equatorial. When this star was placed in the centre of a field of about 45′, no stars above the tenth magnitude were visible. But, in this case, what has become of No. 6142 of the Paramatta Catalogue, rated 7·8 m.? Mr. Tebbutt found the place of his star for 1878·0, R.A. 17h. 30m. 13s·2, N.P.D. 135° 24′ 17″, in which case Brisbane's star would be distant 16′·8 on an angle of 193°, and should therefore have been in the field.

While writing on the subject of variable stars, we may mention that the *Annuaire du Bureau des Longitudes* for 1878 contains very full lists and ephemerides of these objects, which have been ably prepared from Prof. Schönfeld's catalogue and other sources by M. Lœwy, who now has charge of the popular French work. In other respects the *Annuaire* for the present year is to be recommended as a valuable repertory of scientific facts and data.

The Royal Observatory, Brussels.—M. Houzeau, the successor of the late M. Quetelet in the direction of this establishment, has issued his report on the work of the year 1877. The Observatory is at present in a transition state, the instruments which have long been in use being about to be replaced by others of greater capacity. A meridian circle, almost entirely similar to that constructed for the new Observatory at Strasburg, has been ordered from Repsold; and Dent, of London, supplies the standard sidereal clock, to be accompanied by a chronograph: various modifications have been introduced into these instruments after careful consideration. A refractor of 38 centimetres aperture is in course of construction by Merz, the object-glass having already arrived at Brussels. The ancient meridian instruments have been employed on the observation of stars exhibiting decided proper motion, a work long pursued. On the mounting of the large refractor, M. Houzeau proposes to fix his attention upon three principal objects:—1st. Micrometrical measures of a certain number of double stars—binaries, and those which are affected with rapid proper motion. 2nd. To observe, with particular care, the passages of the satellites of Jupiter across his disc, and their occultations and the transits of their shadows. 3rd. Spectroscopic observations, for which a smaller refractor will also be available. Meteorological observations which have occupied much of the time of the observers during M. Quetelet's superintendence, will be continued, but in a department distinct from that devoted to astronomy, a very necessary arrangement if observations of a routine nature are not to be allowed to interfere with those of a higher class.

A Forecast of the Satellites of Mars.—In the last number of the *Astronomische Nachrichten*, Prof. von Oppolzer, of Vienna, draws attention to the curious passage in the "Travels into Several Remote Nations of the World by Lemuel Gulliver"—of Swift, which he transcribes from the edition of 1755. A correspondent of the *Times* referred to the same passage soon after the discovery of the satellites of Mars by Prof. Asaph Hall became known in this country. We read "they have likewise discovered two lesser stars or satellites which revolve about Mars, whereof the innermost is distant from the centre of the primary planet exactly three of his diameters, and the outermost five; the former revolves in the space of ten hours, and the latter in twenty-one and a half; so that the squares of their periodical times are very near in the same proportion with the cubes of their distances from the centre of Mars, which evidently shows them to be governed by the same law of gravitation that influences the other heavenly bodies." This idea of Swift's, which appears to have only recently come to the knowledge of Prof. v. Oppolzer, is so singular a one taken in connection with the facts of the discovery of the satellites of Mars, that it is not surprising the editor of the *Astronomische Nachrichten* should have transferred it to his columns. Possibly the opinion which has prevailed largely amongst astronomers that, if satellites of Mars existed, they must be very small and close to his disc, may have had originally some connection with Swift's fancy.

BIOLOGICAL NOTES

PAPUAN PLANTS.—In the Appendix to Baron von Mueller's "Descriptive Notes on Papuan Plants," which we have just received we find some interesting addition to orders already considered, and which we have had occasion to refer to before. In Leguminosæ, *Acacia holosericea* is recorded from Geelvink Bay, found by Beccari; from the Fly River, by D'Albertis; and Baxter's River, by Reedy. In Myrtaceæ are four additions—*Tristania macrosperma*, *Myrtella beccarii*, *M. hirsutula*, and *Bæckea frutescens*. A remarkable myrtaceous plant, with the habit of a *Psidium*, is stated to be contained in Dr. Beccari's collection, which Baron Mueller thinks is probably referable to the genus *Eugenia*. The only flower available for examination had eight petals, being double the number of the calyx lobes. Unless this augmentation arose from monstrous growth we are reminded that we have here a species abnormal not only in the genus *Eugenia* (and to which the name of *E. pleiopetala* might be given), but also in the whole order of Myrtaceæ, except *Gustavia*. From Mount Arfak, at an elevation of about 6,000 feet Dr. Beccari obtained the first epacrideous plant recorded from New Guinea, though in all likelihood others will yet be detected in the higher mountain regions.

HORSE-SHOE CRABS.—With reference to the fact that large numbers of trilobites are found on their back, and the inference that when living they probably swam in this position, Mr. Alex. Agassiz states (*Silliman's Journal*) that he has for several summers kept young Limuli (horse-shoe crabs) in his jars, and has noticed that besides often swimming on their backs, they will remain in a similar position for hours, perfectly quiet, at the bottom. When they cast their skin it invariably keeps the same attitude on the bottom of the jar. It is not uncommon to find on the shores, where Limuli abounds, hundreds of skins thrown up and left dry by the tide, most of which are turned on their backs. Again, young Limuli generally turn on their back while feeding. Moving at an angle with the bottom, the hind extremity raised, they throw out their feet beyond the anterior edge of the carapace, browsing, as it were, on what they find in their road, and whisking away what they do not need by means of a powerful current produced by their abdominal appendages.

GREEN ALGÆ.—Our knowledge of the life-history of those green-coloured algæ which seem to possess a true reproductive system, is progressing with rapid strides, and in the *Botanische Zeitung* for October and November last two most remarkable papers on two well known (so far as external form goes) species have very considerably advanced our knowledge of the group. The earlier in date (October) of these two memoirs is by the well-known botanists Rostafinski and Woronin on *Botrydium granulatum*. This alga was described by Ray nearly 200 years ago, and is probably known to many as growing up in damp clayey spots, and presenting the appearance of bright green blobs about the size of large mustard seeds. Common as this plant is, it is only now that after several years' consecutive watching the authors have been able to clear up the mystery of its life, and to determine that the formation of ordinary zoospores can eventuate in the four following ways (*a*) from the vegetative plant, (*b*) from an ordinary zoosporangium, (*c*) from the root-cells, and (*d*) from a Hypnosporangium: and as still further means of increase we have (*e*) cell division, (*f*) formation of spores, and (*g*) formation of isospores. Botrydium would also seem to enjoy a five-fold resting state: 1. The asexual aquatic zoospores with a quiescence of one month. 2. The root-cells, quiescence the year through in which they are formed. 3. The hypnosporangia, quiescence the same. 4. The spores, quiescence a year. 5. The isospores, quiescence at least over the year in which they were formed. The next memoir is a joint one by A. de Bary, the able editor of the journal, and E. Strasburger, and is about that very beautiful green seaweed not uncommon in the Mediterranean, called *Acetabularia mediterranea*. This genus was so called by Lamouroux on account of the saucer (acetabulum) like form assumed by the little rows of filaments that crown the cylindrical stalks. There are three species known, perhaps they may be all varieties of the one now referred to. Prof. de Bary was only enabled to watch the progress of the spore development to a certain stage, but by Strasburger's researches, carried on at Spezia, we are enabled to read the whole history and to know that the motile bodies of protoplasm set free from a mother-cell, can and do conjugate, forming a resting body which can and does vegetate. At the close of this memoir Strasburger proposes that we should call the body formed by the conjugation of the contents of two cells (Gametæ) by the name of Zygote, and that those plants whose Gametæ are active might be called Planogameta, and those where (as in Desmids) the Gameta are at least quasipassive, might be called *Aplanogameta*.

DEEP SEA ASCIDIANS.—Mr. H. N. Moseley has published (*Transactions*, Linnean Soc. S.S. Zool., vol. 1) a description, accompanied by excellent figures, of two very remarkable forms of ascidians. The first described was obtained from the great depth of 2,900 fathoms in the North Pacific Ocean, and is called *Hypobythius calycodes* in allusion to its occurrence at so vast a depth and to its cup-like form. Its outer skin is hyaline and extremely transparent, but in certain places it is strengthened by the presence of tough cartilaginous plates, and these are arranged in a nearly symmetrical manner. It is attached by means of a stalk. It is probably allied to the genus Boltenia, but is abundantly distinct from all known forms. The second is a beautiful stellate form taken 1070 fathoms, not far from one of the Schouten Islands. From its having eight long radiating processes it was at first taken for a medusoid form. Its test is hyaline and gelatinous and it is also an attached form, but the stalk is short. The respiratory sac is flattened out so as to become nearly horizontal, and there is no gill net-work present. It has been called *Octacnemus bythius*.

THE BYSSUS IN THE MUSSEL.—Tycho Tulberg has published in the *Transactions* of the Royal Society of Natural History of Upsala (July, 1877) an account of the structure of the byssus-forming gland in *Mytilus edulis*. The strong silky threads formed by this gland, which moor the mussel shell so firmly to its resting-place, must be familiar to most. In an allied genus (Pinna) these threads have been even spun and formed into gloves. The manner in which the tongue-like foot can affix these threads is easily to be seen by watching a small specimen of the common mussel when in a healthy condition and confined in a glass jar. The minute structure of the gland that secretes the threads is well described by Mr. Tulberg, who promises further to publish an account of the structure of this organ in some other species of byssus-forming bivalves.

AQUATIC RESPIRATION.—Some experiments on the breathing of aquatic animals (both fresh and salt water) have been recently described by MM. Jolyet and Regnard in the *Archives de Physiologie*. The results are briefly as follows:—These animals, living in a medium very poor in oxygen, and having a blood-liquid with small respiratory capacity, have the least vigorous respiration. In the free natural act of respiration the oxygen which disappears is not exactly represented by the oxygen in the carbonic acid produced; the ratio $\frac{CO_2}{O}$ is always less than 1; *i.e.*, aquatic animals, in the normal state, never give off more carbonic acid than the oxygen they absorb. (The opposite result got by some physiologists is attributed to keeping the animals in an enclosed medium whose oxygen they gradually exhausted.) As with other animals, heat-variations in the surrounding medium has a marked influence on the chemical phenomena of respiration. Taking 2° and 30° as the limits of bearable external temperature, the quantities of the absorbed oxygen vary (other conditions being equal) in the ratio of 1 to 10. Among other causes which may have an influence on the vigour of breathing (apart from those connected with species) the most important, after temperature, are the state of hunger and digestion, the amount, and the greater or less intensity of muscular action. In the experiments there was sometimes a slight development of nitrogen, sometimes an absorption. No definite opinion could be expressed with reference to this point.

GEOGRAPHICAL NOTES

EXPLORING COLONIES.—The Société des Colons Explorateurs, lately organised in Paris, is developing a most healthful degree of activity. Its purpose is to organise a systematic method of exploration and colonisation, based on the same principles as those which animate the newly-founded international society for the exploration and civilisation of Africa, but embracing in its field all the undeveloped portions of the globe. The Society has formed two councils to direct its operations. In the first, which is charged with the scientific, geographical, and exploratory sections, we notice the names of Malte-Brun, de Lesseps, de Quatrefages, Milne-Edwards, Admiral La Roncière le Noury, &c. The second, devoted more especially to agriculture, commerce, and industry, embraces Michael Chevalier, Tisserand, Col. Solignac, F. Garnier, and other well-known names. The plan adopted by the Society for the attainment of its objects is eminently practical. A colony is formed from representatives of various classes and occupations, who are well fitted to investigate and develop the resources of a new country; it is provided with a complete equipment, and despatched to a promising locality. Here a firm foothold is established, and the new settlement made, as soon as possible, not only self-supporting, but a centre for geographical and general scientific investigation. The band of permanent colonists are accompanied by a certain number, who, after obtaining a degree of familiarity with the difficulties to be overcome in a new settlement, are ready to form the nucleus of a new colony. In this manner not only will the various colonies increase the sphere of their activities at a rapid rate, but drill at the same time groups of hardy explorers well fitted to extend the circle of the Society's undertakings. The first experimental colony has already been started on the coast of Sumatra, and embraces in its *personnel* graduates of the leading technical and professional schools of Paris. If this simple practical programme is carried out successfully, it is evident that the new Society, increasing the extent of its operations in arithmetical progression, will soon become a most important factor in the slow process of civilising the world.

SUMATRA.—In the January session of the Dutch Geographical Society it was announced that Lieut. Cornelissen had been appointed to take charge of the Sumatra exploring expedition, lately deprived by death of its commander, M. Schow-Sandvoort. He leaves in March to assume the direction of the explorations. During the past three months 14,000 guilders have been contributed for the Sumatra exploring fund.

NIAS ISLAND.—In Petermann's *Mittheilungen* for February is a very full account, with map, of the Island of Nias, on the west of Sumatra, by Dr. A. Schreiber. The island now belongs to the Dutch, and by them has in recent years been pretty thoroughly explored. The island is hilly, the highest summit being 2,000 feet, the formation being mostly sandstone and coral.

ARCTIC EXPLORATION.—Admiral La Roncière le Noury in his capacity of president of the Paris Geographical Society, M. Quatrefages, and M. Maunoir, general secretary, have written an official letter to Capt. Howgate, U.S.A., conveying to him their approbation of his scheme for establishing a polar colony in Lady Franklin Bay. They trust this document may induce the Congress to vote the required credit for starting the contemplated expedition. They express, moreover, their gratitude for the sending out of Capt. Tyson's preliminary expedition, and they trust Capt. Howgate will soon be in a position to take advantage of the means which his hardy lieutenant has been sent to collect. Capt. Howgate has written to the Danish Government, asking them to send instructions to the Disco authorities, authorising them to place the Government storehouse at the disposal of Capt. Tyson, if he has failed in collecting a sufficient number of furs during the present winter season. Mr. S. R. Van Campen has been asked by the Hon. B. A. Willis, of the Committee on Naval Affairs in the United States Congress for a report on the Arctic expeditions abroad, and has complied with the request. Besides speaking particularly of the proposed expeditions of Holland and Sweden, Mr. Van Campen suggests to the Committee, as it has in charge the bill now before Congress for an American expedition, proposed in accordance with Capt. Howgate's scheme, the incorporation of a clause granting rewards upon a graduated scale to individual explorers of whatever nationality, who may reach latitudes or make discoveries in Arctic territory beyond points hitherto attained.

ROHLFS' EXPEDITION.—Herr Gerhard Rohlfs has received no less than 300 applications for participation in his expedition to the Libyan Desert. Of course the great traveller can only consider very few of them. We learn further that he intends also to explore the Shari, Binue, and Ogowai Rivers and their tributaries. We hope he will succeed in accomplishing this, as it will solve many of the questions raised by Stanley's discovery of the course of the Congo. The date of his departure is not yet fixed.

SPITZBERGEN.—A very interesting series of nine maps of Spitzbergen, partly rare and little known, are published in the *Tijdschrift* of the Amsterdam Geographical Society, with an essay by Capt. de Bas, on the geographical names of Spitzbergen. The maps begin with that of Barentz's third voyage of 1596, followed by those of Gerritz, 1612; Edge, 1625; Middlehoven, 1634; Daniel, 1642; two others of 1648, and the latter half of the seventeenth century; that of Johannes van Keulen, 1710, and finally the Dunér-Nordenskjöld map of 1864.

JAPAN.—In the *Monatsbericht* of Petermann's *Mittheilungen* for February, Dr. Behm gives some information concerning recent geographical work in Japan. There is an itinerary by Dr. Schulz, of a journey he made in

August, 1877, from Tokio to Hatsuishi (Nikko), and from Nikko to Takasaki; an account of the observations made by Dr. Naumann last summer during a journey into the little known western part of Nippon, and another at the same time into the north of that island by Herr Gebauer; and some information from the *Tokio Times*, by Y. Watanabe, on Chikuzen, a province in the north-west of the Kiushiu.

NOTES

THE following grants have just been made from the Research Fund of the Chemical Society to aid the carrying out of the following researches:—50*l*. to Dr. Wright, of St. Mary's Hospital Medical School for the continuation of his researches in chemical dynamics; 25*l*. to Dr. Armstrong for an investigation of camphor and allied compounds; 20*l*. to Dr. Carnelly, of Owens College, Manchester, for a research on the hydrocarbons diphenyl, ditolyl, &c., and their derivatives; 10*l*. to Mr. P. Phillips Bedson, of Owens College, Manchester, for a research on derivatives of phenyl acetic acid, and on the constitution of isatin; and 5*l*. to Mr. J. R. Crow, of Owens College Manchester, for a research on the action of zinc ethyl on the chloride of vanadium.

WE regret to announce the death, at Nice, of the celebrated Danish conchologist, Dr. A. L. Morch.

WE hear with great regret, from an Italian correspondent, that the well-known astronomer, Father Secchi, has been seriously ill for several weeks, and that little hope is entertained of his recovery. The Roman correspondent of the *Times* states, however, that Dr. Ceccarelli, who is attending him, does not absolutely despair of his recovery. Father Secchi is not yet sixty, and is of robust frame.

AT the General Monthly Meeting of the Royal Institution on Monday, Dr. Warren De la Rue, D.C.L., F.R.S., in the chair, the special thanks of the members were given to Mr. William Bowman, F.R.S., for his present of an ivory bust of Prof. Faraday, by the late Matthew Noble, M.R.I. In reference to the telephone which Mr. Preece had explained to the members last Friday, the chairman stated that he had made attempts to measure the current produced by the vibrations of the disc of iron in front of the magnet of the telephone, and that he was unable to detect any by means of a most sensitive dynamometer which would render evident the current of a Daniell's cell through 2,000 ohms. Moreover, by other experiments made by other means, he concluded that the current produced did not amount to that which a Daniell's cell would send working through 100,000,000 ohm resistance.

THE New York *Tribune* gives an account of a public exhibition in that city of Eddison's Phonograph, which seems to have been very successful. The tones reproduced by the vibrating disk of the machine were so distinct that they could be heard and understood in different portions of the crowded room. Words spoken in a high key and with forcible emphasis were reproduced with much greater distinctness than those spoken in a low tone, even when the latter were uttered very loudly. A difference in the sound of different voices could be easily discerned. Several fragments of songs were sung in a high key and repeated by the machine with wonderful fidelity. The inventor stated that the machine has yet to be perfected before its full power is developed, and that ultimately it can be used to receive and reproduce the songs of popular singers as they are rendered on the stage.

AT a recent meeting of the Royal Society of Edinburgh, in connection with a letter from New York describing the phonograph, Sir William Thomson gave some explanation of the machine. All previous attempts to record sound were, he said, founded on the motion of a style or marker at a true parallel to the paper. Mr. Eddison's ingenious invention of the electric pen was different. It consisted of a fine point, which, by an excessively rapid vibration perpendicular to the paper, caused by a small electric machine connected with two thin wires to the point, left a trace of any person's handwriting in a row of very fine holes, from which the handwriting could be printed. Mr. Eddison, from this invention, elaborated the phonograph. By the greater or less pressure produced through the action of the alternate condensation and expansion of the air caused by the mechanism of the voice, the diaphragm operated upon the point and recorded the sounds. It was the most interesting mechanical and scientific invention they had heard of in this century. There could be no limit to its application. A man could speak a letter through the phonograph—it would be recorded on tinfoil, sent in an envelope through the post, and his friend, by applying the point of the phonograph to the tinfoil, could reproduce the words and tones uttered. In fact they could take down the singing of a Titiens (had we one), which might be reproduced to a tone two hundred years hence.

BOTH Houses of Legislature have unanimously passed a resolution giving the thanks of the U.S. Congress to Mr. Henry M. Stanley for his achievements in the field of African exploration. Mr. Stanley meets the Geographical Society in St. James's Hall to-night. It would be interesting to know how many applicants beyond the 2,000, which the hall will hold, have been disappointed. The officials of the Society have had a trying time of it in attending to the loads of applications they have received. Mr. Stanley will be entertained at dinner by the Society on Saturday.

IN connection with the recent election of Prof. Simon Newcomb as a foreign member of the Royal Society, it was stated that previous to that Prof. Asa Gray was the only living American who enjoyed that honour. We find, however, among the list of foreign members the name also of Prof. Benj. F. Peirce, of Cambridge, Mass.

WE have received an interesting volume: "Estudios sobre la flora y fauna de Venezuela," by A. Ernst. The author, in two ably written articles, gives a general idea of each of the two large kingdoms as they appear in Venezuela, and further adds some details on the fungi, orchids, molluscs, and birds of that country. The book is published at Caracas, and consists of over 100 quarto pages.

THE first meeting of the Institute of Chemistry of Great Britain and Ireland was held on Friday afternoon at the rooms of the Chemical Society, Burlington House. Prof. Frankland, F.R.S., the first President, read an address in which he gave an account of the origin of the institute. At a dinner given to Prof. Canizzaro on the occasion of his visit to London in May, 1872, Prof. Frankland drew attention to the increasing importance of chemistry in relation to the wants of communities, and suggested the usefulness of an institute that should be to chemists what the Colleges of Physicians and Surgeons are to the medical profession, the Institute of Civil Engineers is for civil engineers, and the Inns of Court are to the legal profession. Although the need of experts in connection with water and gas analysis, legal proceedings, and nuisances was recognised, and the application of chemistry to agriculture and manufactures was known to be of great importance, the suggestion was not taken up in a practical way until the beginning of 1876, when a meeting to consider the subject was held at the rooms of the Chemical Society on April 26. A committee was appointed to draw up a scheme for the constitution of the institute, which was laid before a meeting held in November. At one time it was thought that the objects might be effected by establishing a separate branch of the Chemical Society with the Fellows of the Chemical Society. After much discussion the formation of the present institute was decided on. The institute has power to appoint examiners as to the fitness of candidates for its membership. Prof. Frankland, in the course of his address, drew attention to the fact that under the Pharmacy Act of 1868 no one, not even the President of the Chemical Society, may call himself a chemist unless he is duly registered as a pharmaceutical chemist. There are already 225 members and 142 associates, and a fund of over 1,000*l.* for the new institute.

The Naturwissenschaftliche Gesellschaft of Jena celebrated the twenty-fifth anniversary of its foundation on January 17 last. Upon that occasion Mr. Charles Darwin, Prof. M. I. Schleiden, of Wiesbaden, and Prof. Oscar Schmidt, of Strasburg, were named honorary members of the society.

Further information shows that the earthquake of Monday, January 28, was felt at several places in London, at Ryde, Osborne, Southampton, and Lyme Regis. Shocks were felt in Neumarkt at 10 A.M. on the 27th and 5 A.M. on the 28th. At Judenburg (Upper Styria) two different shocks were felt on the 27th, at 10.6 A.M., and on the following day at 4.32 A.M. At Waldshut, on the Rhine, in the Grand Duchy of Baden, an earthquake was felt on the evening of January 16 shortly before midnight. The shock lasted about a second and seemed to proceed in the direction from south-west to north-east. Subterranean noise was plainly audible. The same phenomenon was simultaneously observed at Alb, Karsau, Beuggen, Schopfheim, and other places in Baden, as well as in all the north-westerly cantons of Switzerland.

The recent investigations of Sergius Kern, resulting in the discovery of davyum to which we have had occasion frequently to refer, are being submitted to a careful examination in the Heidelberg laboratory under the direction of Prof. Bunsen. The results so far coincide with those of the Russian chemist, and it is to be hoped that the entire research may stand the crucial test of the leading authority on the platinum metals.

M. Pictet delivered, during the past week, two very interesting addresses in the laboratory of the École de Médecine, before the chemists of Paris, in which he gave a very complete and detailed description of his late experiments on the liquefaction of gases. He is a young man of scarcely thirty, an easy and fluent speaker, and made a pleasant impression on his Parisian auditory. A *brochure* of 100 pages, which he has just issued, with drawings, gives a very elaborate description of the whole series of experiments on the compression of gases.

The Hon. Rollo Russell sends us some notes on experiments he has made which go to prove that there is no need to insulate the wires connecting a pair of telephones, at least when used for short distances. No. 18 uncovered copper wire was laid along grass and trees 418 yards, the two lines being kept well apart. Articulation and a small musical box were very well heard. The same wire buried for three yards in wet clay, the lines being about 5 ft. apart and the telephones 20 yards apart, gave good results, and it appears that the bare wires may be taken under roads, &c., without diminution of the audible effect. With the same wire taken across a pond, the lines being submerged in water about 40 yards, and lying on the grass the rest of the distance about 28 yards—the wires were about a yard apart in the water—conversation in low tones was distinctly heard when not overpowered by the noise of a strong wind blowing at the time. Probably No. 18 copper wire, uninsulated, might be laid across rivers and straits and used for telephonic purposes without appreciable loss of sound, as Mr. Russell, not in any of the above cases, noticed a feebler effect than with insulated wires.

Interesting antiquities have recently been excavated at Neumagen on the Moselle. The Roman poet Ausonius mentions in his "Mosella" that the Emperor Constantine possessed there a "beautiful castle," which was doubtless destroyed about the middle of the fifth century when Treves was several times ravaged by the Franks. About a century afterwards the famous castle of Nicetia was built by the Archbishop Nicetius, who probably utilised the foundations of the old Roman structure. Nicetia was rased to the ground in the year 881 by the Normans. Many of the old foundations are now being again excavated and are tolerably well preserved; the materials of which they are constructed are sandstone, marble, and limestone.

M. Marié Davy has published, through Gauthier Villars, the Montsouris Observatory's Meteorological *Annuaire*. The volume contains a number of important improvements.

The first ordinary meeting of the newly-established Physical and Chemical Section of the Bristol Naturalists' Society was held on January 22 in the Library of the Bristol Museum. A paper was read by Mr. W. W. Stoddart, F.C.S., F.G.S., "On a Remarkable Occurrence of Indican in the Human Body." A paper was then read by Mr. S. P. Thompson, B.Sc., B.A., of University College, Bristol, "On Vortex Motion in Liquids." The paper was illustrated by experiments showing the production of smoke rings in air and of rings of coloured liquid in water. The author had lately tried the action of electromagnetism upon the rings projected through water and had observed their retardation and partial destruction in passing through a powerful magnetic field. His experiments are at present incomplete.

The third volume of C. L. Michelet's "System der Philosophie als exacter Wissenschaft" (Berlin: Nicolai) will shortly be published. It will contain the philosophy of the mind. The fourth volume will treat of the philosophy of history and will close the interesting and elaborate work.

Experiments with a new telegraph apparatus have lately been made at Vienna, by means of which some 100 or 120 messages may be sent by a single wire in the remarkably short space of one hour. Under certain conditions this number may even be raised to 200 or even 250 messages. The inventor of the new apparatus is Herr August Eduard Granfeld, an Austrian telegraph official. At the end of December he presented to the Austrian "Telegraphenanstalt" eight working and two principal apparatus of his invention for practical trials. The experiments were crowned with complete success.

A new watchman-controlling clock has been constructed by Messrs. Fein at their telegraph works at Stuttgart, which on a single dial records the times at which a watchman visits any given number of stations however far apart, as well as the succession in which they are visited, and thus also the intervals which elapse while the man is proceeding from place to place. The same firm has constructed an automatic alarum for uninhabited or locked localities.

It is stated that such enormous quantities of snow are now lying in the Austrian "Salzkammergut" as have not been seen there for the last fifty or sixty years, and a sudden thaw is dreaded extremely, as it would unavoidably cause enormous inundations. News from Pesth reports that on January 27 the Danube broke through the dykes at Domsod, and caused a vast inundation in Kumania, for a distance of some fifty miles, as far as Baja. Nine villages are under water. Other inundations are reported from the valley of the Vesdre River in the eastern part of Belgium.

An exceptionally mild winter is reported from the north-western States of North America. In the districts near St. Paul, Minnesota, the farmers ploughed their fields in Christmas week. On Christmas Day excursions were made by steamer on the Mississippi River. In former years the river was generally frozen over on that day.

THE Vienna Society for the Protection of Animals offers a prize of thirty ducats in gold for the best pamphlet recommending the protection of animals. The little work must be of general interest and must be written specially for teachers. It must be in the German language and is not to exceed six sheets in print. Competitors must send in their manuscripts, on or before July 1 next, to the Committee of the Society at Vienna (Johannesgasse, 4).

IN the *Geographical Magazine* for January and February will be found Language Maps of India and Further India, including the Indian Archipelago, with accompanying text, by Mr. Robert Cust. Mr. Cust announces that he is collecting materials for a language map of Africa. Such a map already exists in Stanford's "Compendium of Geography—Africa," constructed by Mr. A. H. Keane, who, besides, gives there material for such a map to which, we should think, it would be scarcely possible to add. Is not Mr. Cust's work one of supererogation?

THE *Geographical Magazine* or February contains a curious and interesting autobiography of an Eskimo, Hans Hendrik, who served in the Arctic expeditions of Kane, Hayes, Hall, and Sir George Nares. It was written in Eskimo and translated by Dr. Henry Rink, who writes an introduction.

ETHNOLOGISTS will be interested in a paper in the February number of the *Geographical Magazine*, by Fr. A. de Roepstorff, on the inland tribe of the Great Nicobar. The author concludes that this tribe is certainly not Negrito, the specimen he saw having Mongolian characteristics.

THE mathematical reader will peruse with interest the eleventh number of the *Bulletin* of the Belgian Academy of Sciences (vol. xliv.), where he will find a paper by M. Ghysens, on the determination of volumes and superifices, being the application of an ingenious and new general formula to several difficult and interesting problems; an interesting note by Prof. Catalan, on a new principle of subjective probabilities; and a first paper by Prof. Folie, on the extension of the notion of the anharmonic relation.

THE movements of sediments in the sea it has been common to regard as exclusively an effect of wave-motion. M. Fuchs has recently pointed out that while this is an obvious cause, it is not the only one. Another factor (and one which is probably more powerful in its action), consists in the accumulations which the water undergoes periodically, partly through the flood-tide, partly through winds prevailing on the coasts. Suppose the sea on a coast heaped up ten to thirty feet (and this is not uncommon), the hydrostatic equilibrium must be thereby greatly disturbed, and a current must arise in the depths from the point of greater to that of less pressure, *i.e.*, from the coast to the deeper parts. If a calculation be made of the excess of weight caused by such accumulations of water, such enormous sums are obtained that it is easy to see how the current generated will be strong enough to move not only fine detritus, but large blocks, towards the depths.

THE additions to the Zoological Society's Gardens during the past week include a Banksian Cockatoo (*Calyptorhynchus banksii*) from New South Wales, presented by the Lady Ellesmere; a Common Badger (*Meles taxus*) from Scotland, presented by Lord Saltoun; a Brown Bear (*Ursus arctos*) from North Europe, presented by Mr. J. N. Allen; a Yaguarondi Cat (*Felis yaguarondi*), two Yarrell's Curassows (*Crax yarrelli*), two White-bellied Guans (*Ortalida albiventris*), a White-fronted Guan (*Penelope jacucaca*), a Common Trumpeter (*Psophia crepitans*), a Sun Bittern (*Eurypyga helias*), an American Kestrel (*Tinnunculus sparverius*), all from South America, purchased.

AMERICAN SCIENCE

THE eighth paper of Prof. Loomis' interesting series of "Contributions to Meteorology (*American Journal of Science and Arts* for January, 1878), treats of the origin and development of storms, violent winds, and barometric gradient, the data being obtained from the United States Signal Service observations. Of forty-four different storms recorded between September, 1872, and May, 1874, twenty-one (nearly a half) appear to have originated on or very near the chain of the Rocky Mountains (the others were of various origin). More than two-thirds of the whole originated north of latitude 36°. (We refer to this subject elsewhere.)

This number of the journal also contains some observations by Capt. Belknap, of the *Tuscarora* (during her cruise in the Pacific) proving once more that a cold stratum may exist in the ocean between two warmer ones above and below. The case occurred off the Kurile Islands, between 40° and 52° N. lat. and 158° and 167° E. long. The upper part of the stratum in one place, showing a temperature of 33°·7 F., was only twenty fathoms below the surface, while at ten fathoms below the surface the temperature was 41°. At a depth of 100 fathoms the temperature was 32°; below that curve to a depth of 200 fathoms the range of temperature was from 34°·5 to 38°·7. The width of the cold stratum gradually narrowed to a point in an easterly direction from the coast, or as the edge of the Japan stream was approached. (Several data are furnished regarding the currents in that region.)

An able revision of the atomic weight of antimony has lately been carried out by Mr. Josiah P. Cooke, jun., and the first portion of his paper to the American Academy on the subject is here given in abstract. A new mineral, pyrophosphorite, an anhydrous pyrophosphate of lime from the West Indies, is described by Prof. Shephard, jun. Prof. Rockwood furnishes notices of some recent American earthquakes; and Maria Mitchell, observations on Jupiter and his satellites, with the equatorial telescope at the observatory of Vassar College. Attention may also be called to a summary of the field work of the United States Geological and Geographical Survey of the Territories, under the charge of Dr. Hayden, for the season of 1877. The surveys in Colorado having been completed during the previous year, the parties prosecuted their work in a belt of country lying mainly in the western half of Wyoming, but also embracing adjacent portions of Utah and Idaho. Among other important results, Dr. White has demonstrated the identity of the lignitic series of strata east of the Rocky Mountains in Colorado with the Fort Union group of the Upper Missouri River, and with the great Laramie group of the Green River basin and other portions of the region west of the Rocky Mountains. The botany of the Survey was represented (it is known) by Sir Joseph Hooker and Prof. Asa Gray. Mr. Jackson has visited the strange ruins found in Northern New Mexico and Arizona, and procured the necessary data for plastic representation of the pueblos, or communal town dwellings, of Taos and Acoma, models of which he has constructed. Contact with Europeans has somewhat modified their ancient style of building, but one can readily see that they are constructed after their ancient prototypes, the dwellings of the forgotten people; forgotten, because the builders of the modern structures are as ignorant of the ancient builders as we are ourselves.

The first number of the *American Journal of Mathematics* will be published early this month, with contributions by Prof. Simon Newcomb, Mr. G. W. Hill, Mr. H. T. Eddy, Cincinnati, O., Dr. Guido Weichold, Zittau, Saxony, Prof. Cayley, Mr. H. A. Rowland, Prof. Charles S. Peirce, Prof. Sylvester, and Mr. William E. Story.

We recently announced that the *American Naturalist* has been removed to Philadelphia for publication under the management of Prof. Cope. This, with other new conditions, has given dissatisfaction to a number of the old contributors. This dissatisfaction has taken definite form and is expressed in a circular as follows:—"The undersigned, who have in past years contributed articles and by other means helped to support the *American Naturalist*, protest against the continued use of their names in the same connection under the new conditions advertised in the December number of 1877." The circular is signed by Profs. Agassiz, Gray, Whitney, Hagen, Shaler, Allen, Farlow, Dana, Marsh, Verrill, Newberry, Grote, and Lockwood.

PRIZES OF THE PARIS ACADEMY OF SCIENCES

THE following is a complete list of the prizes awarded by the Academy at its annual meeting, January 28.

The two great prizes in mathematics and physics were not awarded this year.

In mechanics the Poncelet prize was awarded to M. Laguerre for his mathematical works; the Montyon prize to M. Caspari for his work on Chronometers; the Plumey prize to M. Freminville for his improvements in steam-engines; the Fourneyron prize to M. Mallet for his tramway engine.

In astronomy the Lalande prize was given to Prof. Asaph Hall, the discoverer of the satellites of Mars; the Vaillant prize to M. Schuloff for his method of detecting the small planets; the Valz prizes to MM. Paul and Prosper Henry for their star maps.

In physics the Lacaze prize was awarded to M. A. Cornu for his researches on the determination of the rate of light.

In chemistry the Jecker prize was awarded to M. A. Houzeau for his researches on the production of ozone; the Lacaze prize to M. Troost for his many valuable chemical researches.

In botany the Barbier prize was divided between M. Galippe for his toxicological studies on cantharides, MM. Lepage and Patrouillard for their services to medicine and pharmacy, and M. Manouvriez for various physiological researches. The Desmazières prize was divided in part between Dr. Quélet for his work on the fungi of the Jura and the Vosges, and M. Bagnis for his memoir on the puccinia. From the Bordin prize an encouragement of 1,000 francs was awarded to M. Charles Eugène Bertram for his work on the lycopodiaceæ; another Bordin prize was awarded to the same botanist for his work in connection with angiosperms and gymnosperms.

In anatomy and physiology the Shore prize was awarded to M. Jousset de Bellesme for his researches on the physiology of insects.

Among prizes in medicine and surgery, one of 2,500 francs was given to Prof. Hannover, of Copenhagen, for his work on the retina of man and the vertebrates; 1,500 francs to Dr. Topinard for his work on anthropology.

In physiology the Montyon prize was divided between Prof. Ferrier and MM. Carville and Duret. The Lacaze prize was given to M. Dareste for his researches on the artificial production of monstrosities.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Smith's Prizes have been adjudged as follows:—First prize, John Edward Aloysius Steggall, B.A., Trinity, second wrangler, 1878; second prize, Christopher Graham, B.A., Gonville and Caius College, third wrangler, 1878. By this award it will be seen that the senior wrangler has failed to secure either of the Smith prizes, an unusual circumstance, which has only occurred seven times since the foundation of the prizes by Dr. Smith in 1769, viz., in 1770, 1830, 1859, 1867, 1874, 1875, and again this year.

EDINBURGH.—The Falconer Memorial Fellowship in Palæontology and Geology, of the annual value of about 100*l*., tenable for two years (and, under certain conditions, for a longer period), is now vacant, and is open for competition by graduates in Science or Medicine of the University, of not more than three years' standing at the time of the competition. Names of candidates must be sent, on or before the 1st of April, to the Secretary of the University, from whom further details may be obtained.

The Shaw Fellowship in Mental Philosophy, of the annual value of about 170*l*., tenable for five years, will be open to competition in December next by graduates in arts of either of the four Scottish Universities, of not more than five years' standing at the time of the competition, and by all students of the said Scottish Universities, who, although they have not graduated in arts, have successfully passed all the examinations necessary for graduation in arts within the period of five years before the time of the competition. Candidates must give their names and addresses to the Secretary of the University before December 1.

PRUSSIA.—The ten Prussian universities cost yearly 7,146,000 marks (357,000*l*.), of which sum about two-thirds is contributed directly by the State. This amount is divided as follows:—Berlin, 1,334,700 marks; Bonn, 712,500; Königsberg, 668,600; Breslau, 620,300; Kiel, 478,800; Marburg, 430,400; Halle, 368,800; Göttingen, 268,600; Greifswald, 135,600, and Münster, 102,500. The Saxon Government has difficulty in inducing its parliament to bestow its usual annual grant of 700,000 marks on the University of Leipzig, the argument being advanced that only one-third of the students were natives of the kingdom.

FRANCE.—The new Ministry is making rapid strides in the direction of general education. In a law lately laid before the Chamber of Deputies, we notice an appropriation of 120,000,000 francs, which is intended to serve for the erection or purchase of over 27,000 new school-houses, as well as their equipment.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 12, 1877.—On the laws according to which gases spread in liquid, viscous, and solid bodies, by M. v. Wroblewski.—On the galvanic resistance of selenium, by M. Forssmann.—On the relation of the electric conductivity of selenium to heat and light, by M. W. Siemens.—Influence of light on the electric resistance of metals, by M. Hanseman.—On the significance of polarisation for the electric behaviour of liquids, by M. Herwig.—On a mode of inference employed by M. Clausius in the electrodynamic theory, by M. Zöllner.—Supplement to a paradox of the mechanical theory of heat, by M. Ritter.—On the Crookes's radiometer, by M. Hankel.—On the perception of colours, by M. Weinhold.—On the composition of æschynite and samarskite, by M. Rammelsberg.—On the inventor of the plate of the air-pump, by M. Gerland.—Supplement to "Studies on Chemical Volumes," by M. Ostwald.

Reale Istituto Lombardo di Scienze e Lettere, Rendiconti, vol. xi. fasc. xvii.—Memoir of Prof. Giuseppe Ferrari.—Reports of the classes, announcement of prizes, &c.

Fasc. xviii.—Experiments with regard to the action of heat on the radiometer, by M. Hajech.—Researches on differential equations, by M. Casorati.—On seismic movements in the valley of Chiana and their influence on the hydrographic condition of the valley of the Tiber, by M. Verri.—On a peculiar horny growth, by M. Sangalli.

Journal de Physique, December.—Telephones, by M. Niaudet.—On a new apparatus for measuring the frequency of periodic movements, by M. Marey.—Continuity of the liquid and the gaseous state of matter, by M. Bouty.—Study on the formation of the negative photographic image, by M. Lermontoff.

Morphologisches Jahrbuch, vol. iii., Part 4.—R. Wiedersheim, on the cranial skeleton of Urodela, ninety pages, four plates, dealing with Siredon, Amblystoma, Salamandra, Chioglossa, Triton, and the Salamandridæ generally.—W. Salensky, on the budding of Salpæ, fifty-four pages, 3 plates.—W. Rauber, on the last spinal nerves and ganglia.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, January 9.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—Ephraim Brunt, T. W. Cowan, and Henry Fox were elected Fellows of the Society.—The following communications were read:—On the great flat lode south of Redruth and Camborne, by Dr. C. Le Neve Foster, B.A.—On some tin-mines in the parish of Wendron, Cornwall, by Dr. C. Le Neve Foster, B.A.—On some of the stockworks of Cornwall, by Dr. C. Le Neve Foster, B.A.—The precarboniferous rocks of Charnwood Forest, Part II., by the Rev. E. Hill, F.G.S., Fellow and Tutor, and the Rev. T. G. Bonney, F.G.S., Fellow and late Tutor of St. John's College, Cambridge. The authors described the result of the microscopic examination of a considerable series of the clastic rocks of Charnwood. Many of these, even among the finer beds, prove to be of pyroclastic origin. The coarser are generally composed of a ground mass of pulverised felspar, with viridite and some iron peroxide, full of larger fragments of felspar crystals (generally both of orthoclase and plagioclase) and lapilli. The structure of these is often distinct, some are certainly andesites, others some kind of trachyte; slaty fragments are also present, and occasional grains of quartz. The authors express their opinion that all the larger felspar crystals, and most, if not all, the quartz grains, are of clastic origin, even in the more highly altered varieties. Some of the larger fragments in the breccias were examined, and referred in part to devitrified trachytes not very rich in silica. The igneous rocks were then described. The syenites of the southern and northern districts were shown probably to belong to one system of intrusion. The hornblendic granite of the Quornden district was also described, and the microscopic structure of the different varieties of it and the above investigated. A number of igneous rocks generally forming dykes in these was described; some appear to be altered basalts, others andesites, one is a felsite, another a diorite. A group of outlying igneous rocks in the vicinity of Narborough was described. Of these, one is a quartz feltsite with some hornblende; another varies between this and a quartziferous syenite; the rest are syenites, and one contains so much plagioclase as to be almost a diorite. One of the above, near Enderby, is seen to be distinctly intrusive in an altered slaty rock, which the authors have no doubt belongs to the Forest series. This discovery proves the igneous character of these rocks also, and extends the area of the slaty series five miles further south than was previously known. A section was devoted to the faults of the Forest region. Here the principal fault runs along the anticlinal axis, with a downthrow on its eastern side which diminishes from 2,500 feet at the north end to 500 feet at the south end. East of this the beds seem undisturbed, but on the west they are shattered by many faults, whose course cannot be traced. These are most numerous near Whitwick. The anticlinal fault is pre-carboniferous. In conclusion, the age of the clastic and of the igneous rocks was discussed. The authors inclined to the opinion that the former are of the same age as the Borrowdale series of the Lake district (lower Silurian), but admitted that the recent discovery of agglomerates in the pre-Cambrian rocks of Wales, and in the probably pre-Cambrian ridges of the Wrekin district, weakens the arguments for this correlation. They do not think that there is any reason for supposing them Cambrian. If the Charnwood series is lower Silurian, they think it most probable that the syenites and the Quornden granite were intruded in some part of the old red sandstone period, and that the later dykes were very probably post-carboniferous but pre-triassic.

Meteorological Society, January 10.—Mr. H. S. Eaton, M.A., president, in the chair.—The Council, in their Report, express their gratification at the increase in the number of the Fellows and stations of the Society, the greater size of the *Quarterly Journal*, and the higher value placed on it by foreign scientific societies, the augmentation of the library, and the addition to the sum hitherto contributed by the Meteorological Council, as well as at other evidences of vigour and progress manifested during the year. The number of Fellows now amounts to 417. The president then delivered his addre During his tenure of office the alliance between the Meteorological Council and the Society had been further cemented, the Society supplying the Government with certain statistics, and getting some assistance from the Council in return. This arrangement had been completely successful, and the president considered it calculated to foster the growth of climatic meteorology under the auspices of the Society, and likely to remove any jealousy on the part of the public towards a governmental department so peculiarly constituted as the Meteorological Council. After criticising some of the work undertaken by the last-mentioned body, Mr. Eaton exhibited curves of the results of the hourly observations of the barometer and thermometer for the year 1876 at Valentia, Armagh, Glasgow, Aberdeen, Falmouth, Stonyhurst, and Kew, these being the stations established in 1868 for determining the meteorological constants of the British Isles. The curves showing the combined diurnal and semi-diurnal variation of atmospheric pressure might be referred to one of two distinct types. In one of them the minimum of pressure was most pronounced in the morning, in the other the afternoon. The former type was found at the maritime stations of Valencia and Falmouth, the latter at inland stations such as Kew. The diurnal range of the temperature of the air was closely related to the pressure. It was least at the maritime stations, reaching only 4°·8 at Falmouth, and attaining a maximum of 9°·3 at Kew.—The following gentlemen were elected Officers and Council for the current year:—President: Charles Greaves, M.Inst.C.E., F.G.S. Vice-Presidents: Henry Storks Eaton, M.A., James Park Harrison, M.A., Robert James Mann, M.D., F.R.A.S., Charles Vincent Walker, F.R.S. Treasurer: Henry Perigal, F.R.A.S. Trustees: Sir Antonio Brady, F.G.S., Stephen William Silver, F.R.G.S. Secretaries: George James Symons, John W. Tripe, M.D. Foreign Secretary: Robert H. Scott, M.A., F.R.S. Council: Hon. Ralph Abercromby, Arthur Brewin, F.R.A.S., Charles Brooke, F.R.S., Edward Ernest Dymond, William Ellis, F.R.A.S., Rogers Field, B.A., M.Inst.C.E., John Knox Laughton, F.R.A.S., Rev. William Clement Ley, M.A., Richard Strachan, Henry Samuel Tabor, Capt. Henry Toynbee, F.R.A.S., George Mathews Whipple, B.Sc.—A resolution was passed to the effect that ladies be admissible as Fellows of the Society.

Physical Society, January 19.—Prof. G. C. Foster, president in the chair.—The following were elected Members of the Society:—J. Angell, Lieut. G. S. Clarke, R.E., T. F. Iselin, M.A., J. W. Russell, M.A.—Mr. W. H. Preece read a paper on some physical points connected with the telephone. This instrument may be employed both as a source of a new kind of current and as the detector of currents which are incapable of influencing the galvanometer. It shows that the form and duration of Faraday's magneto-electric currents are dependent on the rate and duration of motion of the lines of force producing them, and that the currents produced by the alteration of a magnetic field vary in strength with the rate of alteration of that field; and further, that the infinitely small and possibly only molecular movement of the iron plate is sufficient to occasion the requisite motion of the lines of force. He pointed out that the telephone explodes the notion that iron takes time to be magnetised and de-magnetised. Mr. R. S. Brough has calculated that the strongest current employed in a telephone is $\frac{1}{\text{[illegible]}}$th of the C.G.S. unit. Mr. Preece explained that the dimensions of the coil and plate depend on the strength of the magnet, but the former should always consist of fine wire and be made as flat and thin as possible. The adjustment of the position of the magnet (as near as possible to the plate without touching) is easily effected by sounding a vowel sound *ah* or clearly and loudly; a jar is heard when they are too near together. After briefly enumerating the attempts which have been made to improve the instrument, he mentioned the various purposes to which it can be applied. In addition to being useful in the lecture room, in conjunction with several well-known forms of apparatus, it forms an excellent detector in a Wheatstone bridge for testing short lengths of wire, and condensers can be adjusted by its means with great accuracy. M. Niaudet has shown, by employing a doubly wound coil, that it can be used to detect currents from doubtful sources of electricity, and it is excellent as a means of testing leaky insulators. Among the facts already proved by the telephone may be mentioned the existence of currents due to induction in wires contiguous to wires carrying currents, even when these are near each other for only a short distance. Mr. Preece finds that if the telephone wire be inclosed in a conducting sheath which is in connection with the earth, all effects of electric induction are avoided; and further, if the sheath be of iron, magnetic induction also is avoided, and the telephone acts perfectly. A great number of experiments on the use of the instrument on telegraphic lines were then described, from which it appears that conversation can be carried on through 100 miles of submarine cable, or 200 miles of a single wire without difficulty, with the instrument as now constructed. The leakage occurring on pole-lines is fatal to its use in wet weather, for distances beyond five miles. An interesting series of telephones was exhibited, and by means of one of very large dimensions Mr. Preece showed that the currents produced by pressing the centre of the plate sensibly affect a Thomson galvanometer, and that the motion of the needle ceases in a remarkably instantaneous manner as soon as the pressure is removed, a necessary condition in order that the receiving-plate should accurately reproduce the motions of the sending-plate. In the discussion which followed, Mr. R. Sabine suggested that the failure of all attempts at improving the instrument by increasing its dimensions might be due to the *damping* action of the permanent magnet on the plate, the strain on it being proportional to the size of magnet and rendering it less sensitive to the sonorous waves. Mr. Coffin pointed out how interesting it would be if, instead of employing a receiving-instrument, the currents could be communicated directly to the auditory nerves, and Prof. Adams explained the relation subsisting between the character of the vibrations of the disc and the character of the electric currents to which they give rise.—Dr. Lodge described a simple form of apparatus for determining the thermal conductivity of rare substances, such as crystals, which cannot be obtained in slabs or rods. It consists of two small tin cans with a copper arm about eight inches long projecting horizontally from each, the external ends being clean and flat. They are placed in a straight line with the crystal between them, and held together by a slight horizontal pressure. Holes are drilled in the copper rods for thermometers, and the curves of temperature being given by these, that for the intermediate crystal can be at once calculated.

Victoria (Philosophical) Institute, January 21.—Prof. Lias, of St. David's College, read a paper on Matthew Arnold and modern culture.

February 4.—The Right Reverend Bishop Cotterill read a paper upon scientific thought and religious belief.

Institution of Civil Engineers, January 22.—Mr. Bateman, president, in the chair.—The paper read was on some recent improvements in dynamo-electric apparatus, by Dr. Higgs, Assoc. Inst. C.E., and Mr. Brittle, Assoc. Inst. C.E.

MANCHESTER

Literary and Philosophical Society, December 11, 1877.—Mr. E. W. Binney, F.R.S., president, in the chair.—Note on the daguerreotype portrait taken of the late Dr. Dalton, by J. B. Dancer, F.R.A.S.—Note on metallic niobium and a new niobium chloride, by Prof. H. E. Roscoe, F.R.S.—On the retention of saline impurities by hydrated ferric oxide, by Mr. Charles Frederick Cross, Dalton Scholar in the Owens College. Communicated by Prof. H. E. Roscoe, F.R.S.

December 26.—Mr. E. W. Binney, F.R.S., president, in the chair.—Notice of a large boulder stone at Old Trafford, Manchester, by E. W. Binney, F.R.S.—On the geometrical representation of the equation of the second degree, by Charles Chambers, F.R.S., Superintendent of the Colaba Observatory, Bombay. Communicated by J. A. Bennion, F.R.A.S.

EDINBURGH

Chemical Society, January 16.—Mr. W. Inglis Clark, B.Sc., vice-president, in the chair.—A paper was read by Mr. John Gibson, Ph.D., F.R.S.E., on yttrium and erbium, being the second part of an historical sketch of the rarer elements.

January 30.—Mr. Newton Burns presiding.—Papers were read by Mr. G. Carr Robinson, F.R.S.E., on the solid fatty acids of cocoa-nut oil, and by Messrs. Robinson and Thomson on the composition of gases from lime-kilns.

PHILADELPHIA

Academy of Natural Sciences, July 3.—Prof. G. A. König, on protovermiculite, a new micaceous mineral from Arkansas, $R'_2R''Si''_2O'_{12} + H_2O$, related to jefferisite and colsagecite.

July 24.—Mr. J. A. Ryder, on colour variation in mammals. The distribution of colour in wild and domestic animals was compared, showing that bilateral symmetry of colouring is interfered with in some way by domestication, wild animals almost invariably being symmetrically coloured.

July 31.—Dr. Rothrock, on the poisonous properties of the Leguminosæ.

August 14.—Prof. G. A. Konig, on strengite, from Virginia. This mineral, $Fe_2P_2O_8 + 4H_2O$, was discovered in cavities in dufrenite.

August 28.—Dr. D. J. Jordan and W. S. Brayton, on Lagochila, a new genus of catostomoid fishes, known in Georgia as the Hare-lip Sucker.

WELLINGTON

Philosophical Society, August 4, 1877.—W. T. L. Travers, F.L.S., M.H.R., president, in the chair.—Dr. Hector drew attention to several interesting additions to the museum, which were arranged on the table. Among the most important was a handsome bird from New Guinea, the *Goura victoria*.—Mr. Kirk also called attention to a log of black maire, a species of olive (*Olea apitila*), sent by Mr. Elliotte, of the Pakuratahi, which, on account of its great hardness, is much used as blocks and cogs in machinery.—Capt. Edwin read a letter from Mr. Rawson, on the reciprocity of seasons, the character of the seasons in Europe being followed by a similar season in Australia and New Zealand. Mr. Carruthers thought that even in New Zealand the seasons did not agree; and Dr. Hector said it would be necessary to fix upon the one place for comparison, as seasons were not uniform, a moist season on the east coast being frequently a dry season on the west coast. Dr. Newman considered that the seasons were affected all over the world by sun-spots.—Mr. McKay then read a paper on gold found in the Mackenzie district of Canterbury; on which subject Dr. Hector added some interesting information regarding the occurrence of gold generally in that district, and pointing out that Mr. McKay's observation that the gold and associated quartz were found only in the last formed moraines and alluviums, confirmed his theory that the retirement of the glaciers was chiefly due to the erosion of the mountains.

VIENNA

Imperial Academy of Sciences, December 13, 1877.—On the present state of the water question, by M. Wex.—On the anatomy of the African elephant, by M. Mojsisovics.—The electrical after-currents of transversally magnetised iron bars, by M. Streintz.

December 20.—The protoplasm of the pea, by M. Tangl.—On a new apparatus for direct volumetric determination of the moisture of the air, by M. Schwackhofer.—Elementary deduction of the complete formula for determination of the tone of vibration of a mathematical pendulum, by M. Pscheidl.—Contribution to knowledge of cupric chloride, by M. Rosenfeld.—On the air-pressure at Vienna, with supplemental remarks on the temperature of Vienna, by M. Hann.

GOTTINGEN

Royal Academy of Sciences, November 3, 1877.—Attempt at a theory of electric separation through friction, by M. Riecke.

December 1.—Report of the Secretary (126th anniversary).—Obituary notice of von Baer.—Announcement of subjects for prize competition, &c.—On the formation of the volcano of Fuego in Guatemala, and account of an ascent of it, by M. von Seebach.—On the origin of language, by M. Benfey.

December 26, 1877.—New geometrical and dynamical constants of the earth, by M. Listing.

THURSDAY, FEBRUARY 14, 1878

MR. STANLEY

SIR SAMUEL BAKER spoke the truth on Thursday night last in St. James's Hall when he told Mr. Stanley that the Prince of Wales might be regarded as the spokesman of the nation when he addressed the great explorer in warm words of welcome and admiration. Not for many years has there been so much excitement in London as there was on Thursday in connection with the wild rumours on the state of affairs in the East; it seemed as if people could not possibly have a shred of attention to bestow on any other matter, but nearly two hours before the time at which the meeting of the Geographical Society was to commence the doors of St. James's Hall were besieged by an eager crowd; and many hundreds, if not thousands, had to be left out in the distribution of tickets. The welcome which Mr. Stanley received could not possibly have been more enthusiastic. In view of the many hard words that have been spoken of Mr. Stanley's conduct under certain trying circumstances, the sight on the platform of the stately figure and genial face of the venerable missionary and explorer, Dr. Moffat, father-in-law of Livingstone, was exceedingly gratifying, showing, as we think it did, that so humane and experienced an "African" as he does not consider that Mr. Stanley has greatly sinned.

That Mr. Stanley should be received with all the enthusiasm of hero-worship by the civilised world is just what might have been expected. It is seldom, however, that a hero receives the glory due to his heroism so promptly as Mr. Stanley has done, especially when that glory has been earned in the field of exploration. Hitherto it has only been through the tardy medium of a book that the public at home have learned of an explorer's work; but in Mr. Stanley's case we have been able to watch his progress step by step by means of the eagerly-looked-for letters he sent home from the heart of Africa, like spectators watching the progress of an assault against a hitherto impregnable stronghold. Thus when Stanley emerged once more into "the light of common day" the very first white man at Emboma into whose hands that memorable appeal for help came knew at once that one of the greatest deeds of all time had been accomplished.

The exact grade to be allotted to Mr. Stanley among the *dii majores* of explorers must be left to a future generation, but this we may be sure of that when the man and his work shall stand clearly out against the "azure of the past," when all the accidental circumstances that accompanied the ever-memorable journey shall have been forgotten, Mr. Stanley will take his place among the foremost of pioneer explorers, as one of the greatest benefactors to humanity and science. He, indeed, has shown that there is work in the world for many generations of men of science, and it will be long after the region has been opened up to commerce ere science will have obtained an adequate knowledge of its treasures.

Mr. Stanley has been termed "the Bismarck of African exploration;" as Bismarck has united into one great empire the fragmentary states of Germany, so has Stanley by the work he has accomplished united into one great whole the *disjecta membra* of African exploration. But the likeness between the two men extends further than this; in the one case as in the other there has been a well-defined purpose carried out by means of a clear and cool head, firm nerve, unflinching will, and (perhaps more important than all) an iron constitution.

What then has Mr. Stanley done to justify the enthusiasm with which he has been universally received by high and low, by learned and unlearned?

One of the most remarkable characteristics of his work is the unprecedented rapidity with which it was accomplished, considering the rich harvest of results. As he told his followers at Zanzibar he meant to do, he shot across the continent like an arrow. In two years and a half, with many zigzags and subsidiary explorations, Africa was crossed from Bagamoyo to the mouth of the Congo. The great work of the expedition, the exploration of the Lualaba from Nyangwe to the sea occupied only five months; looking at it in all its aspects, no explorer ever did so great a work in anything like the time.

For thousands of years has the Nile been a mystery which civilised humanity has never ceased to seek to penetrate; no other geographical problem, not even the pole itself, has had such a fascination for Europe. Many and many a life has been sacrificed in the attempt to find the source of the sacred stream, and it was in seeking this goal that Livingstone wandered away south to find "the fountains of Herodotus," only to find a grave on the marshy shore of Lake Bangweolo. The glory of virtually settling the problem has remained to Livingstone's discoverer and pupil, Stanley. In his march northwards from Ugogo to Lake Victoria Nyanza, the explorer came upon a river which flows into the south of that lake, the river Shimeeyu, about 350 miles long, which may be regarded as one of the most remote, if not the most remote, of the sources of the old Nile. Further, into the west side of the lake flows Speke's Kitangulé river, which Mr. Stanley has re-baptised the Alexandra Nile; this river the latter explored with much thoroughness while staying at the court of the gentle Rumanika. He found it to be a broad lake-river, giving off many lagoons, one of them Speke's Lake Windermere, and having its source in Speke's Lake Akanyaru (now the Alexandra Nyanza) which again has, Mr. Stanley believes, a river of considerable length flowing into its west side, and another coming from the south, having its origin on the east of Lake Tanganyika. Here then, no doubt, we have the ultimate sources of the Nile, which have been sought for since history began. Mr. Stanley, we believe, has virtually set the question at rest, though we are sure he will willingly share the credit of the discovery with Speke, whose geographical instinct was astonishing, and the essential accuracy of whose discoveries have been throughout confirmed by his successor.

For the first time we have, through Mr. Stanley's exploration, an approximately accurate idea of the outline and extent of Lake Victoria Nyanza. Any map of Africa published two years ago shows this lake in a triangular shape, with an offshoot in its north-east corner. Mr. Stanley has broadened it out into an irregular square, with a coast-line of about 1,000 miles in length, studded with islands, many of them inhabited, and its shores peopled by many different tribes.

The geography of the region between Victoria Nyanza and Albert Nyanza may now be plotted with considerable fulness after the work of Mr. Stanley, who, however, was unable to carry out the plan of doing for the Albert what he did for the Victoria. Through one of the valleys which run north and south between the mountains of this region flows another tributary of the Alexandra Nyanza, and on Mount Gambaragara dwell those mysterious fair-skinned people that Speke heard of, but specimens of whom Mr. Stanley actually saw. About the time of Mr. Stanley's visit, we may remind the reader, Signor Gessi explored the Albert Lake, and we believe, to judge from his narrative, was unwittingly driven to its southern shore, about 1° S. lat. Quite recently, as we recorded at the time, Col. Mason has sailed round the lake, and reports it to be comparatively small and land-locked, with no important affluent other than the Victoria Nile.

On Lake Tanganyika Mr. Stanley completed the work of his predecessors. He circumnavigated the lake, and for the first time accurately plotted the outline of its southern part, adding considerably to our knowledge of the people and products of its shores. We have already spoken at some length of his examination of the Lukuga, which Cameron set down on the middle of the western shore as the long-sought-for outlet of the lake. Stanley examined the Lukuga with great care, and concludes that at present it is only a creek, but that as the waters of the lake are encroaching on the shore, either by the rise of the former or subsidence of the latter, the Lukuga will, in a very short time, actually become an outlet. What Mr. Stanley has told us of the lake and the surrounding region is well calculated to whet the curiosity of the geologist and physical geographer. We have already alluded to Mr. Stanley's theory of the past physical history of the region; but even if his knowledge of geology were adequate to the formation of an acceptable theory, he had scarcely time enough to collect the necessary data. Here, at any rate, is a splendid field for the geologists of the future.

Had Mr. Stanley returned home after his exploration of Tanganyika, or had the toss between himself and poor Pocock been "tails to go south" and leave the problem of the Lualaba unsolved, no one would have blamed him, and his work in the Nyanza region would have added very considerably to his previous reputation as an explorer. But his daring dash down the Lualaba is a *coup* that has immortalised him; it has done for him what the publication of "Pickwick" did for Dickens, it has compelled the world to admit that in his own line he is a genius of the first rank. Indeed we cannot but regard the spirit which animated Stanley at this crisis of his journey in Africa as a really heroic one. He himself happily and aptly expressed it in his address at St. James's Hall by quoting the words which Tennyson puts into the mouth of Ulysses, and which he applied to the position of himself and his followers when they were left by their Arab escort on the broad bosom of the Lualaba, at the very gate of the unknown region:—

> "My mariners,
> Souls that have toil'd, and wrought, and thought with me,—
> . . . Come, my friends,
> 'Tis not too late to seek a newer world.
> Push off, and sitting well in order smite
> The sounding furrows; for my purpose holds
> To sail beyond the sunset, and the baths
> Of all the western stars, until I die.
> It may be that the gulfs will wash us down:
> It may be we shall touch the Happy Isles
> And see the great Achilles whom we knew.
> Though much is taken, much abides; and tho'
> We are not now that strength which in old days
> Moved earth and heaven; that which we are, we are;
> One equal temper of heroic hearts,
> Made weak by time and fate, but strong in will
> To strive, to seek, to find, and not to yield."

The mouth of the Congo has been known since the Portuguese, in the fifteenth century, began to creep down the African coast, and Tuckey, in the beginning of the present century, traced it about 150 miles to the lower cataracts. Its origin and course was one of the few, probably the greatest of remaining, mysteries in geography. Long ago the Pombeiros and other travellers came across streams inland from the Portuguese possessions in south-west Africa, which run northwards, and latterly Livingstone made known the great river Lualaba, which, however, against all evidence, he believed to be connected with the Nile. One of the principal streams known, at least since the time of the Pombeiros, is the Casai, a considerable river running northwards, and which some geographers maintained must be the upper course of the Congo. Others again maintained, and the reports of the natives seemed to confirm it, that in the region between Nyangwé on the Lualaba and the sea, was a great lake into which that and other rivers flowed, while some seemed to think that the Lualaba ran southwards, and probably ultimately flowed into Lake Chad. Livingstone, as we have said, thought the Lualaba belonged to the Nile, while Cameron was convinced it was the Upper Congo, but that it flowed almost straight westwards. The solution of the problem was a task well calculated to fascinate a man like Stanley, a task in which all his rare qualities as an explorer would be developed to the utmost, but a task for which he has proved himself easily equal. It is difficult, indeed, to see how the work could have been accomplished for generations except by a man of Stanley's character, and by the method adopted by him. In whatever light we regard this part of his recent work in Africa—whether as a mere exploit, or as a vast addition to geographical knowledge, or in the light of the great results that are likely to follow to civilisation, commerce, and science it has scarcely, if ever, been surpassed in the history of geographical exploration. We have in previous numbers shown the magnitude and importance of this discovery. In the course of a few months, by the daring genius of one man, there has been thrown open to our knowledge a river of the first rank, watering a region of apparently exhaustless resources both for the man of science and the trader. It is about 3,000 miles long, has many large tributaries, themselves affording many hundred miles of navigable water; waters a basin of nearly a million square miles, and pours into the sea a volume estimated at 1,800,000 cubic feet per second. Such a piece of work is surely enough to immortalise a man.

Such, briefly, is the work accomplished in so short a space by the Commissioner of the *Telegraph* and the *Herald*, a work which he set about as a mere piece of business in connection with his calling of special correspondent, but for which Mr. Bennett had the insight to see he was unusually well adapted. A private business enterprise has thus accomplished what the much-instructed and elaborately-equipped expeditions of learned societies have failed to do It would be a pity were Mr. Stanley's exceptional aptitude for the work of exploration allowed to lie fallow. Even in the basin of the Congo much remains to be done, and we doubt if any great results will follow the Portuguese expedition which Mr. Stanley met at Loanda. There is also South America, the centre of which is now more unknown than Central Africa, and which awaits a pioneer like Stanley to show the way to the minute explorer and surveyor. It is stated that Mr Gordon Bennett contemplates equipping a polar expedition, so that we fear he thinks he has done enough for Africa. But whether or not Mr. Stanley again enters the field as an explorer, he has written his name in indelible letters alongside that of Livingstone, on the heart of Africa.

WAS GALILEO TORTURED?

Ist Galilei gefoltert worden? Eine kritische Studie. Von Emil Wohlwill. (Leipzig: Duncker and Humblot, 1877.)

THIS work treats with exhaustive thoroughness a question first raised about a century ago, as early, in fact, as advancing political liberty rendered its public discussion consistent with personal safety, and which has occupied scientific biographers pretty continuously since that time. The author's main object in reopening an issue, which the majority of recent authorities consider as settled in the negative, is to bring into due prominence the bearing on it of fresh evidence rendered accessible only within the last ten years. Up to 1867, though it was known that a detailed official record of Galileo's trial was preserved in the archives of the Inquisition, only a few isolated and questionable extracts from it had been made public. In that year, however, M. Henri de l'Epinois, by permission of the Papal authorities, published *in extenso* the most important of the documents contained in the trial record. These, supplemented by still more recent corrections and additions, which it is unnecessary to particularise here, supplied a body of new evidence bearing more or less directly on the issue whether the Roman Inquisition, in its treatment of the great astronomer, had recourse in any degree to that test of physical endurance which formed a recognised part of its procedure as of that of contemporary secular courts in cases like his.

It was of course to be expected that in documents drawn up exclusively for the use of the Inquisition itself there would occur a number of technical expressions the exact meaning of which would be far from obvious to a reader unacquainted with the details of procedure in the holy office. This accordingly turns out to be the fact, and interposes no slight obstacle to the interpretation of the fresh evidence thus presented. Wohlwill, in order to overcome it, has put himself through an elaborate course of Inquisitional literature, studying minutely the fixed technical forms for conducting suits in the holy office laid down in manuals and instructions published for the guidance of its own officials. It is obvious how firm is the foundation thus to be secured in comparison with the precarious guessing which would otherwise be inevitable. The tasks both of preliminary inquiry and of subsequent application, have been performed with the utmost diligence, accuracy, and sagacity.

It would be impossible, within the limits of this notice, to enter upon the detailed arguments by which Wohlwill supports his views. All that can here be done is to state the chief results at which he arrives, together, where feasible, with some indication of the line by which he has travelled.

The final sentence delivered by the Inquisition in Galileo's case contains a statement that the court had judged it necessary to proceed against him to "the rigorous examination."[1] Libri had, as early as 1841, asserted, on the authority of various inquisitional manuals, and in particular of one entitled "Sacro Arsenale della S. Inquisizione," that "*esame rigoroso*"[2] was exactly equivalent to "torture," and that this passage of the sentence was absolutely decisive of the whole question. Wohlwill shows, by a complete scrutiny of the "Sacro Arsenale," that a "rigorous" examination in most cases meant one conducted under torture, but that this expression sometimes denoted a less severe procedure. It appears that where the course of the preliminary investigation led the judges to suspect that the accused had not stated the entire truth, three distinct and increasingly intense trials of fortitude and endurance were prescribed for successive adoption. First the prisoner was brought into the ordinary hall of audience and told briefly and sternly that unless he could make up his mind to confess the truth, recourse would be had to the torture. If this produced no result, he was next carried into the torture-chamber, where the use of the various instruments was explained to him, or he was even seized by the attendants, stripped of his clothes, and bound upon the rack, so that nothing remained but to set its machinery in action. In this situation he was again invited to save himself by confession. If he still remained firm, the infliction of the torture at once ensued. The two preliminary appeals to terror were described as the "verbal scaring" (*territio verbalis*), and the "real scaring" (*territio realis*), while the words "rigorous examination" were reserved, strictly speaking, for the final scene of actual agony. It is clear, however, from passages of the "Sacro Arsenale," that in certain cases confessions elicited by the second method of proceeding were described as made under the rigorous examination, though this laxity of expression is explicitly stated not to extend to the first. The text of the sentence against Galileo therefore implies, at the least, that he was carried into the torture-chamber and submitted to some form of the *territio realis*.

The same authoritative document informs us what was the general character of his replies under this ordeal. He answered "in a catholic manner," *i.e.*, denied that he held the reputedly heretical doctrines attributed to him. While stating this fact the Court were careful to insert a saving clause that the answers so given were not to prejudice other points admitted by or proved against the accused. The significance of this clause, which preceding writers appear to have passed unnoticed, is, according to Wohlwill, as follows:—So great was the regard professed by the Inquisition for assertions steadfastly adhered to under the torture, that in regard to whatever formed the actual subject-matter of a rigorous examination, the answers of the accused, if he thus stood by them, had to be accepted as true. It was therefore the interest of the Court carefully to define the limits within which it proposed to allow the accused this chance of escape. The saving clause under consideration was devised for this very purpose, so as to prevent answers made during the rigorous examination from possessing the power of voiding articles of charge or admission not explicitly included in the questions of the interrogating official. Its actual application was, of course, made at the opening of the rigorous examination as a preliminary to the torture, and the fact of the *caveat* being formally recited in the subsequent sentence is held by Wohlwill to confirm his view that Galileo was submitted at least to a *territio realis* in the torture-chamber.

---

[1] "Giudicassimo esser necessario venir contro di te al rigoroso esame."

[2] Wohlwill has shown that Italian, and not, as has hitherto been assumed, Latin, was the language in which the sentence was promulgated.

After this examination of the evidence supplied by the sentence, our author next shows, in opposition to a considerable body of influential opinion, that there was nothing in the circumstances of Galileo's case to negative antecedently the application of torture, and no ascertained subsequent fact inconsistent with its having been inflicted. The absence of any reference to it in his few remaining letters of later date than the trial is completely accounted for by the oath of absolute silence imposed upon all who appeared before the tribunal of the Inquisition. The fact that Galileo was released from the custody of the Court three days after his final examination, and ten days later was able to take active exercise, shows only that severe torture was not inflicted, but by no means excludes the milder form (*leggiera tortura*), to which the Inquisitional manuals distinctly refer. The advanced age of the prisoner, who was at this time seventy, does, it is true, afford a certain degree of presumption in this direction, inasmuch as Inquisitional authorities usually incline to stop at the *territio realis* in the case of aged persons; they give, however, the alternative of applying "a kind of torture suitable to old people," so that this indication is, after all, far from conclusive.

This clearing of the ground is followed by a detailed investigation of the minutes of the trial contained in the Vatican record, so far as they bear on the question at issue. It thence appears that on June 16, 1633, Pope Urban VIII. ordered the prisoner to be interrogated as to his object in publishing his dialogues on the Ptolemaic and Copernican systems, threatened with the torture, and, if this failed to elicit a confession, condemned to abjuration and imprisonment during the pleasure of the Congregation. On June 21 this examination accordingly took place. Galileo was asked whether he held, or had held, that the earth was in motion and the sun at rest. He denied having done so since the decree of the Index on March 5, 1616, and though pressed by his interrogator with the contrary indications afforded by the dialogues themselves and repeatedly urged to tell the truth freely, clung to the denial. On being told that if he persisted further recourse would be had to the torture, he simply reiterated his former statement with this addition: "I am here in your hands, deal with me as you please." At this point the report abruptly terminates with a few words stating that nothing further could be done, followed by the signature of Galileo in attestation of his own deposition. Wohlwill points out that the threat of torture here recorded as delivered in the ordinary hall of audience cannot possibly count as a rigorous examination, since, according to the fixed language of the Inquisition, the latter proceeding did not begin until the officials and the accused had taken up their positions in the torture-chamber. There is therefore a direct contradiction between the sentence, which affirms that a rigorous examination was held, and the official minutes, which relate nothing capable of answering to that designation. It is the deliberately expressed opinion of the German investigator that this contradiction points to a fraudulent tampering with the trial-record, perpetrated at a time when it had become advisable, in the interest of the Roman hierarchy, to obliterate, as far as possible, the traces of a mode of treatment adopted towards the great Italian astronomer which, if once allowed to become notorious, would raise a cry of indignation throughout Europe. In support of this view its author has arrayed a very strong body of evidence, many particulars of which are of singular cogency. It is indeed in this latter portion of his work, where he examines the general claims of the Vatican manuscript to be considered a complete authentic and unaltered record of Galileo's trial, that Wohlwill does the most meritorious service. An attempt to determine to what precise stage of barbarity the Inquisition advanced in its dealings with its illustrious prisoner is after all a matter of secondary interest. On the other hand an energetic effort to ascertain how far the only official account we possess of perhaps the greatest event in the whole history of science is genuine and trustworthy, must be admitted to be an undertaking of signal importance. Enough, and far more than enough, has been achieved in this direction in the present work to excite the gravest suspicions and fully to justify the warning which at its close Wohlwill addresses to the Roman authorities, that in the present condition of affairs only two courses remain open to them; either to appear as accomplices in atrocious frauds, or to bring the whole truth to the light of day Nothing less than a thorough examination of all the remaining original records by competent and trustworthy palæographers can possibly settle the issues now definitely raised.

SEDLEY TAYLOR

The current number (January 16) of the *Rivista Europea*, which reached me after I had completed the above notice, brings a review of Wohlwill's work by Dr. Scartazzini, containing original matter due to his own independent research. The Italian critic has made strenuous use of the latest, and incomparably best, edition of the Vatican manuscript, that by Herr v. Gebler, and arrived at conclusions in regard to the falsification of its text considerably more sweeping than those based by Wohlwill on the less complete information accessible prior to the appearance of v. Gebler's edition. As far as the two writers cover the same ground they essentially agree in their verdict; the difference between them merely being that the Italian theory is more extensive than its German predecessor. It is gratifying to me to find the eminent position among historical critics to which the depth, clearness, and high originality of Wohlwill's writings on this subject in my judgment entitle him, claimed for him with equal confidence by Scartazzini. I regret that the exceedingly technical nature of the new arguments now advanced makes it impossible to give any idea of them here. They aim at pointing out the exact nature of the excisions, transpositions, and other devices by which the Roman forger set to work to eliminate from the manuscript all trace of Galileo's having been, as Scartazzini stoutly maintains that he was, submitted to the actual torture.

S. T.

THE AGRICULTURAL SOCIETY

The Journal of the Royal Agricultural Society of England. Part II., 1877.

THE current number of the Royal Agricultural Society's *Journal* is chiefly occupied with reports of the agricultural exhibitions held during the present summer at Liverpool and at Hamburg, and with reports on farms in Lancashire, Cheshire, and North Wales, which obtained the Society's prizes for good management at the Liverpool meeting. Another report deals with prize farms in Ireland in connection with the competition for small farms instituted by Earl Spencer. Besides these we have two lengthy papers on the American export meat trade, by Prof. Sheldon, of Cirencester, and by Prof. Alvord, of Easthampton, Massachusetts; three papers on village clubs, by Sir E. C. Kerrison, and Mr. Lawes; a paper on the impurities of clover seed, by Mr. Carruthers; and a short report of some investigations on foot-and-mouth disease, conducted at the Brown Institution.

The international exhibition at Hamburg was one of considerable importance: it was devoted exclusively to dairy husbandry. Lying, as Hamburg does, in the immediate neighbourhood of the great dairy countries of Northern Europe, an excellent opportunity was afforded of noting the advance made in dairy work during the last few years. The great improvement which has signalised this period is undoubtedly the use of ice in cream-setting. This invention dates from 1864, and is the work of J. G. Swartz, a Swedish farmer. In the ordinary method of cream-setting the milk is placed in very shallow pans, and stands for thirty-six hours or more while the cream is rising. The milk during this time usually turns sour, and the cream becomes contaminated with free fatty acids, with partially decomposed albuminous bodies, and with other products injurious to the flavour or keeping qualities of the butter. In Swartz's plan the milk, as soon as it reaches the dairy, is placed in deep metal pails, standing in a vessel full of ice. Not only does the low temperature reduce the process of change to a minimum, but, quite unexpectedly, it also greatly facilitates the rising of the cream; so that in pails having sixteen inches' depth of milk the cream is nearly all obtained in twelve hours. The butter churned from this sweet cream is not only very pure in flavour, but has remarkable keeping qualities. This plan, which is rapidly spreading in the north of Europe, and in the United States, is at present scarcely known in England. One obstacle to the general use of the method is undoubtedly the difficulty of procuring a sufficient supply of ice in such a climate as ours. This difficulty has been greatly diminished by the investigations of Prof. Fjord, of Copenhagen. He has shown that snow, if collected after thawing has begun, may be easily trodden into as small a compass as ice, and may be used with equal economy. The collection of snow is also far less laborious than the carting of ice, as the snow may be gathered in the immediate neighbourhood of the homestead. Let us hope that English dairy farmers will not be slow to adopt the scientific methods of their continental brethren.

Statistics regarding the meat-producing capabilities of the United States and Canada are fully given by Profs. Sheldon and Alvord. The number of cattle in the United States is at present about 28,000,000, or three times as many as those in Great Britain and Ireland. The proportion of cattle to population is, in the United States and Canada, about 67 : 100; while in the British Isles the proportion is about 29 : 100. The total area of the farms in the United States is about 8½ times that of the farmed land in the British Isles, while vast tracts of country yet remain to be cultivated. In 1875 the number of acres under Indian corn in the United States all but equalled the whole number of acres under cultivation in our own country.

With such enormous capabilities of production, the only condition wanting for a large export trade is a cheap and efficient means of transit. That such a mode of transit has now been established is proved by the quantities of meat already exported to England. We received in 1876, from New York and Philadelphia, 19,838,895 lbs. of fresh beef; and the trade has so rapidly extended, that in the first four months of 1877 the imports exceeded the whole import of the preceding year, and amounted to 22,812,128 lbs.

The means adopted to preserve so perishable an article as fresh meat during the long journey from America to England is artificial cold. The cattle are slaughtered at the port of embarkation. At the establishment in New York an ox is killed, and the skin and offal removed in the space of three minutes. The carcase is then cooled to 40° F. in a room through which a constant current of cold air is maintained from an ice chamber. After forty-eight hours the carcase is cut up, and placed in the refrigerators of the steamer, and thus conveyed to England. During the voyage a temperature of 37°—40° is maintained, a stream of dry cold air being circulated through the meat-chamber.

The source of cold has hitherto been ice, but a new cooling agent of great power and adaptability promises soon to supersede the use of ice. The invention is due to Messrs. Giffard and Berger, of Paris. In their process air is condensed by a steam-engine, the heat evolved on condensation being removed by a stream of cold water. The cool condensed air is then conveyed to the chamber which is to be refrigerated, on entering which it is allowed to expand again to atmospheric pressure. The cold thus produced is intense. The ease with which the cooling power can be conveyed to distant places, and the fact that ventilation, as well as cold, is accomplished, will probably procure numerous applications for this valuable invention.

For the extension and success of the American meat trade we now only require to erect suitable refrigerating stores, and to provide refrigerating railway-cars, for the safe conveyance and preservation of the carcase after it has reached our shores.

We have no space to refer in detail to the remaining articles. Those who feel an interest in the improvement of the agricultural labourer will find much suggestive matter in the papers on village clubs, while the kindred subject of the improvement of peasant farmers is ably discussed in Prof. Baldwin's report on the Irish prize farms. R. W.

OUR BOOK SHELF

Oregon: its Resources, Climate, People, and Productions. By H. N. Moseley, F.R.S. (London: Stanford, 1878.)

THIS little manual is the result of a visit paid in July and August last by Mr. Moseley to Oregon. Mr. Moseley gives not only the results of his own observations, but has taken the trouble to consult carefully and give the gist of official publications on the state, the result being a thoroughly satisfactory, full, and trustworthy account of the present condition of Oregon. Mr. Moseley has done a public service in undertaking this task, and we recommend his book to all who contemplate emigrating. It will answer nearly every question an intending emigrant is likely to ask, and gives, moreover, very definite advice as to the kind of people for which the state at present is suited. The book contains an excellent map of the state.

A Handbook of Common Salt. By J. J. L. Ratton, M.D., M.C. Madras College. (Madras: Higginbotham and Co., 1877.)

THIS work is not to be judged as a scientific treatise, but as a practical guide to the manufacture of common salt from sea-water. The author has fulfilled the purpose which he set before himself in compiling the book. Starting with a brief historical introduction, he proceeds to lay before the reader a concise statement of the principal chemical and physical qualities of salt. The occurrence of salt as a mineral is then shortly discussed; the analysis of natural salt occupies a small chapter, which is succeeded by others upon the hygienic value of salt, and upon the agricultural uses of the same substance. The principal rock-salt deposits are described, and the mining operations sketched.

After these chapters, which must be considered as introductory, the composition of sea water is discussed; the leading facts concerning evaporation of solutions of mixed salts, and fractional precipitation of the saline substances, are clearly laid down, and upon these the theory of salt manufacture is shown to be based.

Details of the salt manufacture are then given, followed by descriptions of the growth of "spontaneous salt," of the manufacture of salt from brine springs, of "earth salt," and lastly, of salt lakes. The final chapter is devoted to a discussion of the bearings of taxation upon the salt trade.

The book is written from the Indian view-point, and is rich in local illustrations of the manufacture; but the author has endeavoured to make, and we think has succeeded in making, the work a really good manual of general applicability.

The author is to be praised for the carefulness with which he has gathered together and arranged a large mass of facts; the result is a most useful and convenient little book of reference. M. M. P. M.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

The "Phantom" Force

THE famous principles of conservation and dissipation of energy, which have done so much to promote the progress of physical science in recent years, were undoubtedly first inferred and generalised from certain similar laws in the theory of forces which, as we find noticed by Prof. Tait in NATURE (vol. xiv. p. 462), were first propounded by Newton.[1] If in any mechanical system, Newton observes, urged by any forces, to which we must add those which arise from friction, the action of a force reckoned *as a gain* in the system is measured by the product of its impulse and the space through which it is pushed back, or as a loss in the system when the product relates to a space through which the force *is allowed to act*, and if as action of the same kind in the system we also count its gains and losses of actual energy of motion, the whole amount of action in the system remains unchanged during the motion. Viewed from the standpoint of the laws of motion, force, and matter, which Newton starts with in the "Principia," and keeping in mind the special definition here given (coinciding with the modern term "potential increase") of the "action" of a force, obviously the reverse of what would vulgarly be called the action of a force *in increasing* a body's energy of motion, this proposition at first looks like a truism; but the idea of potential energy here coined by Newton[2] is really an essential one; and it besides allows the mode of action of some forces of very common occurrence in nature to be described more simply than they could be without it. The force of gravitation, of attraction and repulsion between two bodies permanently electrified or magnetised, and all dual forces or actions and reactions directed along, and depending only on the distance between two bodies, and not at all upon the time, are of this kind. The force can be completely described in these cases (and it may be looked upon in the first instance as only a measure of convenience) by the permanent gradient of energy-variation everywhere; and hence also by the permanent change of energy from one distance to another, when, as is supposed in this example, the dual force pair acts along the line of centres; since then the changes of actual energy which it produces (acting alone upon the bodies) are independent of the rotation of this line, and may be regarded either as produced with the natural motion of this line's rotation or by the same forces acting along a fixed line of centres. When two such bodies approach, or recede from each other, whatever time elapses or whatever course they may pursue about their centre of mass, not only are the momentary transfers between actual and potential energy equal in energy value at every moment of the motion (for this is *general*, and by this condition *only* the bodies returning twice to the same distance from each other might have very different energies of motion at the two returns); but the whole energy of motion which can be gained between two distances is a definite one, and as this would not be so if the bodies returned twice to the same distance with different actual energies, nor if they returned twice to the same distance with different potential energies, it follows at once that not only is the sum of the actual and potential energies at any one distance invariable with the lapse of time and with any intervening motions of the bodies, but since the gain of actual energy from this distance to any other *is the loss* of potential energy, the sum of these two energies is also the same at one distance as it is at another, and it therefore varies neither with the time nor with the distance of the bodies from each other.

In this illustrative example of two bodies (otherwise unimpelled) exerting upon each other a permanent action and reaction, several points connected with the use of the term "potential energy," as just described, require attention. In the first place, whatever the real forces are (acting in "absolute space"[3]) upon the two bodies, the Newtonian laws of motion establish that their whole effect in altering the energy of motion of the two bodies at any instant is divisible into two parts, that which the forces, removed to the centre of mass of the pair, and acting there on their joint mass, will have on the joint mass in absolute space, and that which is represented by the sum of the bodies' changes of actual energy reckoned in a space which has this centre of the masses for its origin. If we call the latter changes their local changes of energy, and professing ourselves entirely ignorant of motion and position in absolute space, confine our attention to describing the motions of the bodies in the specified or local space, the abstract laws of dynamics again tell us that in this local space the motion of the bodies is what arises from an equal and opposite action and reaction exerted mutually between them. Suppose this to be of the permanent kind above described (which occurs frequently in natural actions, as already mentioned), then as regards the local motion and its forces (now equal and opposite, and quite distinct from what they were abstractly), the above proposition may be predicated of them which asserts that the local energy of motion and local potential energy together have a constant sum. In our circumscribed sphere of observation the energy of motion is entirely known, or in other words, if we follow the bodies along any course from one point to another, not only all the changes and the sum of the changes of their actual energies, but also their energies at first, and therefore their energies at last, are known by a successive process of integration. We know from the permanency of the energy-gradients along the line of centres that the sum of the energy changes between the two given points is independent of the course or lapse of time in which the final point is reached. Instead, therefore, of making a new successive integration for every course, one such integration for all expresses the total change of energy between the points, and as this is possible for all points or configurations which the bodies can reach from their first configuration, if a scale of such energy changes reckoned from some starting one is made out for all the different distances from each other at which the bodies can be, the scale value will be nothing at the starting distance, and will have determined values at all other distances. We would use the scale by saying that the actual energy at any distance only differs from the scale value by the starting-energy to be super-added; or the excess of the actual energy above the scale value is everywhere constant, and everywhere equal to the actual energy at the initial point. This concise description of the motion, as far as the actual energy at any moment is concerned, accords with the mathematical usage of collecting variable quantities thus simply related to each other and to constant quantities on one side, and constant quantities on the other side of an equality; but a further simplification of its expression is effected if those scale values which mean increase of energy from the starting-point are called "negative," and those denoting loss or decrease of actual energy are called "positive"; for having constructed a new scale on this convention (which we may call the negative scale), to use it we must first change the sign of any value in it before applying the last proposition. As that expression tells us that the remainder, on subtracting the former scale value from the actual energy at any point, is constant, this operation of subtraction, after altering the sign of the new scale value, is simply equivalent to adding the new scale value without altering its sign. With this convention, therefore, that an increase of actual energy is a negative increase, or, in other words, a decrease of the negative scale value, we may put the sentence describing the actual energy in every part of the motion in these much simpler words. The sum of the actual energy and of the negative scale value is everywhere constant and equal to the actual energy at the starting-point of the scale, which we may call the initial actual energy. When increase of actual energy coincides with decrease of "negative scale value" (as we have just seen), and also as it is usual to express it with "work done by a force," increase of negative scale value represents work done against a force as it is expressed in the new phraseology of the science of energy, or with "potential work." The actual energy of the material couplet is everywhere fixed and determinate (when it is once started), but if we speak of the negative scale value as "potential energy" the amount of this at various distances depends upon the distance chosen as the initial one, when it is zero. Thus if we reckon the potential energy of a swinging pendulum, drawn by gravitation towards the centre of the earth (whose motions of rotation and of oscillation relatively to the common centre of the globe and of the pendulum-bob may be disregarded, so that, with the exception of gravity, only a force perpendicular to its motion guides the bob in a space, referred to the common centre as origin, which we may identify with the place of the experiment) from the top of the arc, where the actual energy of the bob is zero, this must be the sum of the values of the actual and potential energies throughout the motion, and consequently at the highest point the potential energy is zero, and everywhere else it is negative, while at the lowest point of the arc, where the actual energy is a maximum, the potential energy reaches its greatest negative value. If, on the contrary, we select the lowest point of the arc as the starting-point, and call the potential energy at this point zero, making the sum of the two in all parts of the motion thereby equal to the greatest value which the actual energy can have, the potential energy must elsewhere supply the deficiency as the actual energy abates, or have positive value in all other positions of the bob, and at the highest points of its swing, when the actual energy entirely disappears, it will reach its greatest positive value, equal to the greatest value of the actual energy at its lowest point. By one such system, therefore, the motion is as perfectly described as by the other, and by a different choice of zero-points the individual amount of the potential energy is thus evidently disposable at pleasure, while its difference between two points yet always remains the same. But by taking the zero point where the actual energy has its greatest value, the advantage is obtained, as in the last arrangement for a pendulum, that the potential, like its partner, actual energy, will never be less than nothing, and its values will always be positive. With its zero point so taken, and with a special choice of mass in the moving body attracted or repelled, whose course is followed, the series of negative scale values or of potential energies just described is termed "the potential" or the "potential function" of the force upon it; but its definition for any permanent force-pair supposes the total absence of all such constraining forces as these of the pendulum string, and the bodies must be left perfectly free to approach or recede from each other to the centre, or to the furthest imaginable distance unimpeded by any forces foreign to the pair. In such material couplets it is also sometimes customary to reckon their combined energies actual and potential in a space having for its origin one of the bodies themselves instead of the centre of their mass. The motion of the standard body then disappears, and that of the other body becomes the relative motion of the two, while at the same time a certain mean mass must be supposed centred in the moving body, so that when the product of this, multiplied by its new acceleration, is taken, its impulse relatively to the stationary body (which is now the rate of change of energy of the pair with the distance between them) may not undergo any alteration by the change of origin. Reckoned in this way, either of the bodies may be said to have energies of motion and configuration in the space relative to the other body, whose sum is constant.

---

[1] On reading the passage again (which I here described from memory) I find that its statement is verbally but not substantially different from what I wrote above, and that in Newton's statement the signs are merely taken oppositely. Newton thus describes an "acceleration" (a gain of actual energy) as a "resistance" (*i.e.*, a force) overcome, with a corresponding loss of action in the system. This is the modern view of equivalence between potential and actual "action" or energy, but *with the signs of* these actions changed.

[2] Newton, in fact, anticipated D'Alembert's principle; and if we apply D'Alembert's principle to the motion of a single particle, the way in which it likewise coincides with the modern definition or recognition of potential energy will presently be understood, although it also reverses the signs of both of the energies concerned.

[3] The term "absolute space," or the simpler word "space," used in Newton's enunciations of the laws of motion as the field of action of "force" is nothing more than a space whose origin is either the centre of mass of all the bodies under actual observation, or any space in which that centre is moving uniformly in a straight line. If we extend our observation to new [illegible]und not to be moving uniformly in the original space, the old space must [illegible] given up, and a new one must be adopted (recognising the new masses), to enable us to state all the forces and to describe the motions completely, of all the bodies under observation (which is the sole problem and

(*To be continued.*)

Aid of the Sun in Relation to Evolution

IT is not often that it will fall to the lot of the physicist to harmonise such important theories as those of evolution and the nebular hypothesis, and much credit is due to the boldness and the originality of Dr. Croll's attempt to do this. At the present time the great majority of scientific men hold the truth of both of these hypotheses in spite of the fact that serious difficulties exist in them which admit of only doubtful explanation, so that it is certain they would be considerably strengthened if it were found possible to dovetail them one to the other without unduly straining the conditions of either. That Dr. Croll has effected this important service is, I think, very questionable, although I fully believe it is attainable.

In advocating his own views in NATURE (vol. xvii. pp. 206, *et seq.*), and in his other publications Dr. Croll has anticipated

---

purpose of mechanics) If we continue this process until all the bodies of the material universe are brought, with a knowledge of their masses, under our observation, we reach that abstract field of force, or force-space, which is contemplated in Newton's enunciations. This space may be identified with absolute space, because the centre of mass of the universe by which it is defined is as perfectly abstract and metaphysical an idea as any that we can form of absolute space, on the simple ground that we have no reason to attribute to matter a less boundless and limitless extent in the universe than we ascribe to space itself. To define one metaphysical idea by another is not unscientific, nor is the description of force which Newton gives more repugnant to the eyes of common sense than the ideas which we form, though quite indefinite, of the extent of the material universe, and of the boundless realms of space. A special office, it may also be suggested as very probable, may be assigned to force, to avoid the occurrence of superposition and mingling of matter in the same points of space, or to give matter impenetrability.

two formidable objections which he foresaw would be brought against them, namely, the improbability of two bodies endowed with enormous energy in the form of rapid motion coming into actual collision with one another, and secondly, the want of experience of like movements in the universe. It is but seldom that a theory, however ingenious, can be upheld against *two* antecedent improbabilities, but granting Dr. Croll all he asks, even to the existence of non-luminous bodies moving through space with a velocity of 1,700 miles per second, there may still be brought more serious objections than either of the above. Our knowledge of the actual motions of the stars in space has recently been greatly extended, and it is now well known that proper motions exceeding thirty miles per second are very rare, and that probably there is no well-authenticated case of a velocity greater than forty miles per second. It has long since been ascertained also that the proper motion of our own sun in space is at the rate of four miles per second only. It is, of course, possible or fortunate that the two bodies from whose collision the solar nebula originally derived its vast stores of heat might be of such equal masses and velocities that the motion of translation should be so nearly destroyed, and the whole converted into heat, but it is inconceivable that amid all the diversity of dimensions of the heavenly bodies it should invariably happen that the resultant movement of the combined masses should be reduced to such insignificant figures as the above.

It is strange that it should not have occurred to Dr. Croll that the heat generated by the impact of two bodies in such rapid motion cannot be considered as remaining constant for nearly the length of time he computes, because the rate of radiation from so intensely heated a sun will be enormously greater than it is now. Indeed the origin of the solar heat does not materially affect the question at issue, which is rather of the means of continuous and equable supply than of the primary source. The contraction theory of Helmholtz addresses itself to meet this difficulty, but alone it is probably insufficient. In the *Popular Science Review* of January, 1875, I have directed attention to other possible and supplementary means of heat supply, which, being continuous, will tend to prolong the period during which the radiation of heat from the sun shall be nearly constant, and hence favourable to the development of organic life. Without advocating any peculiar views of my own which recent discoveries have necessarily somewhat modified, I content myself with pointing out what appear to me to be grave difficulties in the way of accepting the theories and explanations of Dr. Croll.

JOHN I. PLUMMER

Nacton, Ipswich

Faraday's "Experimental Researches"

DOUBTLESS many of your readers will have observed an advertisement of a well-known antiquarian bookseller professing to be able to supply "a perfect copy" of Faraday's "Experimental Researches" at a price not too exorbitant for a complete original copy of that priceless work.

Any who may have applied for the work will, perhaps, share with me the indignation with which they discover that the so-called *perfect copy* is only such in virtue of being a "facsimile reprint" (*sic*) not twelve months old, though dated on the title-page 1839. But perhaps scientific men are too innocent of the ways of antiquarian caterers to receive with calm contentment the assurance that they have not been deceived.

SILVANUS P. THOMPSON

University College, Bristol, February 5

CLAUDE BERNARD

IN rapid succession we are compelled to chronicle the recent serious losses by death to French science. To the names of Leverrier, Becquerel, and Regnault, we regret to add that of the equally famous physiologist, Prof. Claude Bernard, who died in Paris on the evening of February 11. He was born at St. Julien, near Villefranche, in the Rhône department, July 12, 1813. After completing a course of study in the Paris faculty of medicine he was appointed hospital-surgeon in 1839. Two years later he became assistant to the well-known physiologist, Prof. Magendie, in the Collége de France, and continued in close connection with him for thirteen years, during the last half of this time lecturing himself as *privat-docent*. A series of notable discoveries made during this period caused his election, in 1854, to the Academy of Sciences, and his appointment to the newly-founded professorship of general physiology in the Collége de France. This he exchanged in the following year for the chair of experimental physiology, a position which he occupied up to the time of his death.

As an original investigator, Bernard stands among the foremost of the century. He entered upon his career at the epoch when Magendie, the chief founder of the modern French school of physiology, had completely altered the character of this study by the introduction of a variety of experiments on living animals, such as the action of the alkaloids, &c. Bernard entered with enthusiasm on the new field of experimental activity opened up by his master, and by a swift succession of remarkable discoveries with regard to the changes taking place in the human organism, guided the young science into a completely new channel. Of these the most important were connected with the phenomena of digestion, and especially the relation of the nerves to these processes. Perhaps the most valuable was the exhaustive investigation into the functions of the pancreatic juice (in 1850), in which he showed that this fluid was the only one in the digestive apparatus capable of so modifying fatty matter that it can be absorbed by the chyle ducts, and that the digestion of this portion of the nourishment introduced into the system was its sole purpose in the animal economy. Another discovery at this period, which attracted universal attention, was that of the saccharine formation in the liver. Bernard found that not only was sugar a normal constituent of the liver, but that while the blood, on entering into this organ, was completely free from saccharine matter, large amounts of the latter could be detected after it left the liver to pursue its way to the heart. Interesting as this fact was, it was eclipsed by the discovery of the two remarkable connections between this function of the liver and the nervous system.

It was ascertained, first that this normal formation of sugar in the liver could be totally interrupted by severing the pneumo-gastric nerve in the neighbourhood of the heart ; and secondly, that by wounding a certain place on the fourth ventricle of the brain, near the origin of the eighth pair of nerves, it was possible to cause such an abnormal formation of sugar that an animal within two hours after such an operation showed all the symptoms of diabetes. In recognition of these brilliant experiments the physiological prizes of the French Academy were bestowed upon Bernard in 1851 and 1853. In a continuation of this line of research in 1859 he made the important discovery that the sugar for the embryo is prepared in the placenta, and not in the liver. Shortly previous to this time he published the results of extensive observations on the temperature of the blood, in which he showed that remarkable alterations in the degree of warmth take place on the passage of the blood from one organ to another, especially in the different parts of the digestive and respiratory systems. The absorption of oxygen by the blood formed the subject of a memoir in 1858, from which it appears that the coefficient of absorption diminishes gradually with an increase of temperature, and becomes zero at 38°—40° C. in the case of mammals, and 40°—44 C. in the case of birds, viz., at the temperatures at which death sets in. The respective amounts of oxygen in the arterial blood, and red and black venous blood were likewise carefully estimated, and the chemical causes for the differences in colour revealed. Among the other leading researches of Bernard must be mentioned those on the comparative properties of the opium alkaloids ; on the poisonous properties of curarine ; on the sympathetic nerves in general ; as well as numerous investigations on the individual processes in the act of digestion. Many of these discoveries, as well as the results deduced from them, have formed subjects for long-continued controversies. With rare exceptions, however, not only

Bernard's experimental correctness, but the soundness of his theoretical deductions, have been universally recognised by leading physiologists.

As an author Bernard was not so fertile as most of the scientists of the present day in France. The few works emanating from his pen are regarded as standard even outside the limits of his own country. This is especially true of his "Leçons de Physiologie Expérimentale Appliquée à la Médecine" (1865), a work valuable not only for the exceedingly thorough, systematic, scientific treatment of the subject, but also on account of the numerous indications for the application in medicine and surgery of the results gained by physiological research. His other works are "Leçons sur les Effets des Substances Toxiques et Médicamenteuses," 1857, "Introduction à l'Etude de la Médecine Expérimentale," 1865, and "Leçons de Pathologie Expérimentale," 1874.

As a lecturer Prof. Bernard was not only peculiarly successful in the professor's chair, but was also distinguished among the *savans* of Paris for his able and lucid presentation of scientific facts to general audiences. He was busily engaged in the fulfilment of his professorial duties when the short sudden disease preceding his death interrupted the courses of lectures, and put an end to a life of rich and varied scientific activity.

As a mark of the universal respect and honour in which he was held, the authorities of the French Republic have decided that his funeral shall be at the expense of the nation.

T. H. N.

A PHYSICIAN'S EXPERIMENT

AT a public lecture at Salisbury Hall, Oxford Street, recently, Dr. T. L. Nichols, of Malvern, related particulars of a "Dietetic Experiment" upon himself, which he had made with a view to solving a difficulty as to the quantity of food per diem which would best sustain health. He had always been temperate, his only excess being to be overworked. He rose between five and six, and worked well through the day, but avoided night-work. He seldom knew pain, never took medicine, and had excellent health. He usually ate twice in the twenty-four hours, at nine and five, because, for him, long rest for the stomach was better than shorter intervals. He appeared to sleep better for not eating after four o'clock. Every one should sleep upon, at least a quiet stomach. He had carefully noted the "dry weight" of the food he had taken, oatmeal, &c., he counted as dry weight. The weight of water forming a large portion of all food had not been reckoned, because it did not supply nutrition. Eggs and milk were perfect foods, but were largely composed of water. Milk was the most perfect food, though not the best for adults. He began on November 5, his food being chiefly bread, fruit, milk, and vegetables. During the experiment he had taken no flesh meat, wine, beer, spirits, tea, coffee, or tobacco. With regard to smoking, if it were the good thing people said it was, why not encourage their wives and daughters to smoke? Medical authorities differed as to the quantity of food that should be eaten, and it was a common belief that the more food we ate the greater would be our strength.

The first week, the lecturer stated, he lived on bread, milk, fruit, and vegetables, the total weight being 3lb. 9½oz., costing 3*s*. 1*d*., *i.e.*, a daily average of $8\frac{3}{14}$ oz., costing $5\frac{2}{7}$*d*.; this was slightly below his standard of 6*d*. a day. He felt better, and clearer, and brighter than usual. The second week he studied quality rather than cheapness, his food being Food of Health, milk and fruit. Total weight 4lb. 4½oz., cost 3*s*. 8*d*., average per diem 9¾oz., costing $6\frac{2}{7}$*d*., and nothing could have been better, physiologically, than the effect of that food upon him. His digestion was simply perfect, and the action of the whole system as good as it could be. He then discontinued milk as unnecessary. For the third week the total amounted to 3 lbs. 2 oz. = 1*s*. 9*d*., giving an average of 7⅐ oz. of food costing only 3*d* per day. Milk was not so cheap for food as Gloster, Dutch, and American cheese; because they had to pay for the water it contained. Doctors recommended 2 or 3 lbs. of food daily to repair the waste of the system; but he asserted that the waste of brain atoms and nerve force could not be measured. The food eaten had to be disposed of at great cost of life and strength, and he believed the wisest plan was to eat the smallest quantity that would properly support the body. The fourth week, his food being similar, weighed 3 lbs 6 oz., costing 1*s*. 2½*d*., giving an average of 8 oz. = 2*d*. per day. He considered 8 oz. the *minimum* and 12 oz. the *maximum* quantity of food that should be taken per day. The total weight of his food during the four weeks was 14 lbs. 6 oz., costing 9*s*. 8½*d*., average per week 3 lbs. 9½ oz.; per day 8¼ oz., costing per week 2*s*. 5*d*., and per day 4¼*d*. He then added soups, puddings, eggs, &c., and the fifth week his food weighed 3 lbs. 12½ oz., costing 3*s*. 4*d*., being at the rate of 8¾ oz., a 5¾*d*. per day. For the sixth week the figures were 63 oz., at 2*s*. 1*d*., or 9 oz. at 3½*d*. per day. He had taken the diet without stimulants and had experienced a constant increase of health and strength and power to work, and his weight had remained at about 12 st. 2 lbs., except that at the end of the fourth week there had been a slight decrease which had since been recovered. The experiment had been fairly made upon an average subject and the results were satisfactory. He was convinced that they ought to give rest to the stomach, and that this would cure all cases of dyspepsia. The diet question was at the root of all diseases. Pure blood could only be made from pure food. Proper attention to diet would reduce the rate of infant mortality and remove many diseases. If the drink of a nation were pure and free from stimulating qualities and the food was also pure the result would be pure health.

SOCIAL ELECTRICAL NERVES

OUR modern Mercury since the year 1846, when the first system of electrical highways was laid down from the metropolis to Norwich, Southampton, Crewe, and Exeter, has not been idle. The wonderful development of the laws enunciated by Wheatstone which regulate the transmission of electric currents through solid conductors has resulted in some very remarkable inventions. At the date at which we write, from a crude beginning when with difficulty electric speech could be conveyed to such limited distances as Manchester and Norwich, we are now able to record the transmission of the Queen's speech to the confines of the empire in a few minutes.

Since the first introduction of private and social telegraphy in 1861, when Reuter first proposed to connect the Reporting Gallery of the House of Commons with the editor's room of each of the leading metropolitan newspapers, the electrical wire has become the means of reducing the cost of newspapers and of sending the news almost simultaneously over the country. Before that time the press paid large sums for "special correspondents," and papers were exceedingly jealous of each other's privileges.

Year by year the public have reaped additional advantages. Submarine telegraphy now includes within its grasp New Zealand, Japan, and the western shores of South America. The private wire system of alphabetical telegraphy between offices and works, carried out over the chief centres of the United Kingdom by Holmes in 1861-5, is in still further process of development. The express speed of the Wheatstone automatic system, duplex and quadruplex telegraphy, and the telephone of Bell, with its delicate electrical sound-wave indications, have all passed into practical existence and become the property of the civilised globe. Still, notwithstanding the advances indicated, much remains to be done.

A recent remarkable advance in the arrangements necessary for utilising the transmitting power of the electric fluid over the metallic nerves of speech we propose to bring briefly under notice.

In every electrical circuit, so far, the limit of usefulness has been restricted to the number of speaking stations or instruments that could effectively be placed in circuit upon the wire, and by the interference and confusion that arises when more than one instrument is used at the same time on such a circuit. To place upon an electrical circuit more than eight or ten instruments has been practically found impossible, the resistance of the instruments themselves being no small element of trouble, while the interference and interruption from multiple speaking has hitherto been found an insuperable difficulty, and one that has greatly tended to clip the wings and usefulness of our modern Mercury. A system that will obviate this trouble and enable any number of instruments to be placed in connection upon the same circuit without the possibility of interference or confusion, opens up a new era in the usefulness of the telegraph as applied to social purposes. It is such a system that will now be described, a system that promises to revolutionise the systems that at present spread over our chief manufacturing cities, and guard the security of property.

A simple illustration will explain the principles of this auto-kinetic system. Let us suppose a tramway to be laid down through the streets and suburbs of any of our large manufacturing centres; the two rails will thread the thoroughfares in every direction, and at each junction, or point of deviation down a bye street or other divergence, a set of points are laid. There is practically no limit to the number of these points that may be placed along the line; they may be one or one thousand. They remain quiescent and of no value as far as the effective running of the car upon the tramway is concerned until the car passes over the special set of points that happen to be required in the transit of the car from its starting-point to its destination. The other nine hundred and ninety-nine sets of points remain ready for use whenever the car has occasion to pass over them, and their presence does not in any way impair the usefulness of the tramway. The one set of points brought into use has been effective in so far that they have enabled the car to reach its destination, and, having been used for a moment, they have again reverted to their original position; while the fact of their being used has in no way affected the utility or efficiency of the remaining points should any be required to pass a car.

Again, suppose two or three cars to be running over various sections of the tramway at the same time, each car could pass over its points on its journey without detriment to the others, although all the cars might be passing points upon the tramway at the same instant of time; the using of these two or three sets of points would not interfere with the remaining 990 odd sets of points which at any moment might also individually be called into requisition. Now the system of electric circuits to be described may be likened to that of the tramway-line, with its accessory junctions and points. A system of two parallel wires is carried through a town. These wires in pairs may be supposed for the purpose of the present explanation to ramify continuously in every direction from a central station up this street and down that, and to embrace within their area the entire commercial and social community. Like the points in the tramway system, so upon the metallic circuit laid down, speaking instruments may be placed at various points and stations along the route, one or 1,000, because in the auto-kinetic system under notice, no instrument is in circuit unless it is, like the points on the tramway-line, being used. A car going over the points makes those points for the time being a portion of the tramway-line. So the circumstance of using the instrument upon the auto-kinetic system makes that instrument for the time being a portion of the electric circuit, and the wires are alone occupied by this transmission.

Should any second or third instrument in other portions of the circuit be brought into requisition at the same interval of time, no interference can take place. As no two cars could run over the same points on the tramway at the same moment, so no two instruments in the system under notice can speak at the same time, but the second or third instrument will automatically succeed the first in the order in which they stand along the line from the central station; just as two or three cars would pass the tram points in the order in which they had been placed upon the line.

The value of this new system of arranging metallic circuits and the instrumental connections, whereby the instrument is only a part of the electrical circuit so long as it is speaking, being thrown off immediately upon the cessation of the speaking current, cannot be estimated or appreciated except by a special reference to its practical development as regards the public and social telegraphy of a large city. This will be fully demonstrated in a subsequent paper by reference to the system of police, fire, and social telegraphs proposed to be shortly carried out for the Corporation of Glasgow, a system at once the most comprehensive and complete that has as yet been devised for affording multiple speaking stations upon the same conducting wires without possibility of interference or confusion.

(*To be continued.*)

OUR ASTRONOMICAL COLUMN

THE STAR LALANDE 19034.—It is somewhat singular that this star, which was observed by Lalande, on March 21, 1797, and then rated 4½m. should have been so little observed since that year. It is not in Piazzi or Taylor, but it was observed three times by Argelander in the Bonn southern zones, viz., Z. 283, March 6, 1850, when it is called 6m.; in Z. 358, February 16, 1851, where we find it estimated 4m., and again in Z. 400, March 8, 1852, where it is 5m. These circumstances taken together appear to point to considerable variability. The star is in an isolated position on the borders of the constellations Hydra and Antlia. The mean of the Bonn observations gives for its position 1850·0, R.A. 9h. 34m. 26·40s., N.P.D. 112° 54′ 41″·0. Lalande's R.A. is one minute less than Argelander's—yet it looks right in the *Histoire Céleste*. Perhaps one of our meridional observers may find opportunity to revise its position and the star may be further recommended to attention on the score of probable fluctuation of light; though it should be remarked that there are other cases of discordant magnitudes in the Bonn southern zones for stars not yet entered on the list of variables, as in η Canis Majoris for instance, for which in three observations the magnitudes are 5, 3, and 2.

VARIABLE NEBULÆ.—Prof. Winnecke in directing attention to the nebula H. II. 278 as probably affording the first indications of *periodical* variability of a nebula, refers to the one discovered in Taurus on October 11, 1852, by Mr. Hind, as affording the single case where astronomers generally have been agreed as to variation. That nebula was detected on the morning of October 11, in one of the most magnificent skies experienced in the Regent's Park, being caught at once in slow sweeping, with the low power-comet eye-piece of the 7-inch refractor. Towards the end of the year 1876, in a fine sky with the same telescope and eye-piece, not a vestige of it was perceptible, and the same result attended several attempts to discern the nebula in 1874 and 1875. Prof. Winnecke mentions that it is not at present visible in our most powerful telescopes.

MINOR PLANETS.—Observers who are still engaged in the exploration of the region of the ecliptic have given signs of much activity of late. First we hear of a small planet detected by M. Perrotin at Toulouse, on January 29, position at 10h. in R.A. 8h. 43m. 13s. N.P.D. 71° 41 twelfth magnitude, which appears to have been independently discovered by Herr Palisa at Pola, on February 1: by an observation at Pola, January 27, it seems this object is not to be confounded with *Rhodope*, No. 166, of which a corrected ephemeris is given in the *Circular* of the *Berliner Jahrbuch*, No. 84, but it is there conjectured that it may be *Urda* No. 167, found by Prof. Peters 1876, August 28. Calculating from the elements of *Urda* in *Circular* No. 64, for the time of the Berlin observation of M. Perrotin's planet on February 3, it results that with the correction $\delta M = + 5^\circ\ 24'{\cdot}9$ the computed and observed longitude will agree, but there is a difference of $- 1^\circ\ 38'$ from the observed latitude which, in the present case, throws doubt upon the presumed identity. Again, on February 2, M. Cottenot, at Marseilles, detected a planet, tenth magnitude, position at 13h. 2m. in R.A., 10h. 2m. 29s. N.P.D., 78° 51′, which was also found by Prof. Peters at Clinton, U.S., on February 4; this object is probably new. Finally, on February 6, Prof. Peters met with another planet, also of the tenth magnitude, in R.A. 10h. 16m. N.P.D. 70° 17′, which he notified to the Paris Observatory through the Smithsonian Institution by cable; it is probable, however, that the presence close to this position of his previously-discovered planet *Antigone*, No. 129, has escaped his attention, and as its brightness would also be about equal to that of stars of the tenth magnitude, it is most likely to be the object observed.

The number of minor planets appears now to have reached 180, and possibly 181.

The Supplement to the *Berliner Jahrbuch*, for 1880, contains ephemerides for the present year, of the small planets to No. 172 inclusive, excepting only *Dike* and *Scylla*, for which the necessary materials are not available. Polyhymnia in opposition on August 30, in 11° S. declination, is distant from the earth 0·88; Atalanta in opposition October 27, declination 37° N., is distant 0·98, and Felicitas in opposition November 11, declination 30° N., is distant 0·92; these are the three cases of nearest approach during the year. Of the minor planets discovered since 1845, Hebe attains the greatest brightness — 7·4 m. in the middle of November, 1878, while in the neighbourhood of ε Eridani.

METEOROLOGICAL NOTES

ATMOSPHERIC MOVEMENTS.—A first paper on this subject, by Mr. Ferrel, has been published by the United States Coast Survey Office, in which the inquiry is limited to an investigation into the mechanics and general motions of the atmosphere which are dependent on wide-spread and periodically-recurring disturbances. In consideration of the enormous difficulties in the way of investigating the effects of friction, the author adopts the only course open to him, viz., to introduce unknown functions into the equations representing the resistances from friction in the direction of the co-ordinates, leaving these to be determined approximately from a comparison of the final results deduced from the equations with observation. From a mathematical examination of the question it is concluded that in whatever direction a body moves upon the surface of the earth, there is a force arising from the earth's rotation tending to deflect it to the right in the northern but to the left in the southern hemisphere; and that this deflecting force is exactly the same for motions in all directions, so that if any sensible effects of this sort arise in the case of rivers or of railroads running north or south, the very same effects must take place where they run east or west or in any other direction. The amount of this deflecting force is exactly double of that which is obtained in accordance with the principle adopted by Hadley. An elaborate examination is made of the distribution of temperature over the earth, the most important of the results being that the mean temperature of the whole surface of the earth is 60°·2, the mean for the northern hemisphere being 59°·5, and that for the southern hemisphere 60°·9. With reference to this result Mr. Ferrel remarks that if important data collected by Dr. Hann for the extreme southern latitudes had been at hand while he was engaged with the investigation, the results obtained for the mean temperatures of the two hemispheres might have been nearly equal. This result, which is essentially different from the commonly received opinion, has, it is obvious, important bearings on many questions of terrestrial physics. The distribution over the globe of atmospheric pressure is similarly examined with results of great importance in their relations to meteorological theories. The coefficient of the annual inequality of pressure in North America amounts to only about one-third of that of the interior of Asia, from which the important conclusion is drawn that the difference between Asia and America in this respect does not depend so much upon the difference in the extremes of temperature of the two continents, which is inconsiderable, as upon the difference in the extent of the two continents. The annual maximum of barometric pressure for the United States, except the Pacific coast, occurs about December 23, which is about sixteen days earlier than in Europe. In both continents the time is considerably earlier than the time of the minimum of temperature. The distribution of temperature and pressure and the prevailing normal winds of the globe are shown on seven well-executed maps. In succeeding papers Mr. Ferrel intends to investigate those disturbances in the distribution of temperature and humidity which are of a comparatively local character, and which result in the locally developed phenomena of cyclones and other storms; and finally to apply the principles of atmospheric mechanics thus developed to the explication of oceanic currents.

CLIMATE OF INDIA.—We notice in a recent number of the *Isvestia* of the Russian Geographical Society, an interesting paper by M. Wojeikoff, being a sketch of the climate of India according to the recent works of Mr. Blanford, the reports of Mr. Wilson, and some notes taken by the author during his recent visit. M. Wojeikoff describes very clearly the main features of the climate, and accompanies his description by some tables which illustrate the prevailing and characteristic directions of the winds. Besides, by a comparison of the temperatures of some places in India and South America, situated the one in parts devoid of forests, and the others in places where the forests are yet preserved, M. Wojeikoff shows what a great influence forests have on climate, and he arrives at the conclusion that the absence of great heats and a continuous humidity of air are always met with at those places which, however far from sea, are situated in forest lands. He concludes, therefore, as to the importance of preserving the forests in India, and expects that detailed observations would yet more show their importance as well as the beneficent influence of the irrigation on climate.

LOW BAROMETRIC READING IN THE HEBRIDES, NOVEMBER 11, 1877.—We have received from Mr. Buchan, Scottish Meteorological Society, a communication on this subject. The following readings of the barometer, reduced to 32° and sea-level, were made by Mr. Youngclause, the Society's observer, at Monach Lighthouse (57° 31′ N. lat., 7° 42′ W. long.), on November 11, at 9 A.M., 28·330; 11 A.M., 28·120; 12.43 P.M., 28·008; 1.30 P.M., 27·912; 4.20 P.M., 27·861; 8 P.M. and 9 P.M., 27·752; and at 9 A.M. of the 12th, 27·968; and at 12·43 P.M., 28·038 inches. Thus for nearly twenty-four hours the barometer at this place was under 28·000 inches, and fell to 27·752 inches, the observer remarking that the rise which followed proceeded at a very slow rate.

At Monach, on November 15, at 12.43 P.M., the barometer was 29·703; 9 P.M., 29·051; 11 P.M., 28 807 inches; after which it began to rise, and at 9 A.M. of the following morning it had risen to 29·828 inches, a fluctuation of nearly two inches having taken place during the twenty hours ending 9 A.M. of the 16th. The storm accompanying this depression of the barometer rose at 10.30 P.M., about the time of lowest pressure to the force of a true hurricane, the worst the observer had ever seen during his twenty years' service as a lightkeeper. At the same dates, at Thorshavn, Farö, the readings of the barometer were—lowest at midnight of the 11th, 28 119 inches; 15th, at 9 A.M., 29·002 inches, and at 9 P.M., 29 350 inches, the barometer thus rising a third of an inch in Farö during the time that it fell about an inch in the outer Hebrides, accompanied by a storm of extraordinary violence, being the heaviest storm experienced in the north-west of Scotland generally for very many years.

Cumulative Temperatures.—To simplify the difficulty of obtaining sums of temperature (a highly important climatological factor, particularly in its application to agriculture) for any district, from the ordinary instruments, M. von Sterneck has recently proposed to obtain these indirectly by observation of the sums of actions produced by the temperature. A suitable apparatus for this we have in the pendulum-clock. The course of this represents the sums of the heat-changes, since it represents the sum of the changes of length of the pendulum, produced by different temperatures, which changes cause variations in the time of oscillation. As the laws of pendulum vibrations and the expansion of substances through heat are known, the true sums of temperature can be deduced from the going of the clock. While the watch-maker is concerned to obtain as uniform working as possible, and uses arrangements to compensate the changes in length of the pendulum, the present case requires that these changes should be brought into prominence; so the pendulum is made of some substance (like zinc) which expands greatly through heat. The clock will reveal the variations of temperature by its slowness or fastness, and by comparing its indications, at certain times, with those of a uniformly-going clock, the sum of divergences of the temperature from any given temperature will be ascertained. The principle of this method can also be applied (as the author shows) to determine the variations in atmospheric pressure and in the intensity of magnetism.

GEOGRAPHICAL NOTES

Brazil.—Mr. Herbert H. Smith has returned to Baltimore, U.S., after an absence of several years employed in scientific explorations in Brazil. Leaving the United States in January, 1874, for Pará, he ascended the Amazon to Santarem, where he was engaged for two years in collecting and studying the insect fauna of that region. Subsequently he extended his explorations to the north side of the Amazon and on the tributary rivers, as far as the base of the great northern table-land. A collection of insects made by him during this period amounted to 12,000 species, with 100,000 specimens, accompanied by copious notes on the habits, geographical distribution, &c. During 1876 and the early part of 1877 he was connected with the Brazilian Geological Commission in examining the geological structure of the country. He succeeded in making a section of the Devonian rocks of the Amazon region, and discovered a rich carboniferous bed on the north side of the Amazon, in the vicinity of Alenguer. The results of this labour are in the course of publication by Prof. Hartt, of the Geological Survey. Several months of his absence were spent in the southern part of Brazil, near Rio de Janeiro and Minas. Mr. Smith has been able to make some interesting inferences in regard to the geological distribution of Brazilian animals. Bates and Wallace have pointed out that the Amazon forms a limit to the migration of many animals. Mr. Smith is of the opinion that the flood plains of the valley, which average forty miles in width, constitute a far more effectual barrier than a body of water of the same breadth. Birds and insects of powerful flight pass this distance without difficulty, and are generally found on both sides; but the sluggish species, especially the wingless forms, like spiders, are generally confined to one side or the other. This is especially shown in those hymenopterous species in which the females are wingless, as the mutillarias, pezomactri, &c. Here the distinction between the northern and southern groups is very striking. The broad alluvial belt through which the Amazon flows constitutes a very distinct zoological province, in which many of the forms appear to have been derived from those of the high land. The contributions of Mr. Smith to geographical knowledge have not been inconsiderable. His maps of the physical geography of the Lower Amazon and of three important tributaries, the Curna, the Mæcurú, and the Jaurucú, are especially noteworthy. The last-mentioned has been entirely lost sight of by modern geographers, though referred to by earlier travellers. This enters the delta of the Xingú close to the Amazon, and is apparently navigable for steamers to a distance of 150 miles from its mouth. Mr. Smith returns to the United States for the purpose of making arrangements for continuing his explorations for several years longer, so as to accumulate a sufficient body of facts to work out satisfactorily the entire problem of the derivation and the geographical distribution of the insects of Brazil.

Africa.—Herr Schutt, who has been despatched by the Deutsche afrikanische Gesellschaft to equatorial Africa, has safely arrived in San Paul de Loando, and starts at once for the interior to complete the work of exploration commenced by Eduard Mohr, whose untimely fate we lately recorded. The series of geographical lectures in Berlin, delivered under the auspices of the Afrikanische Gesellschaft, was opened on January 23, by Dr. Nachtigal, who gave a graphic description of the African kingdom Darfur, which was conquered in 1874 by the Egyptians.

Arctic Exploration.—We learn from *L'Explorateur* that Mr. Gordon Bennett, of the *New York Herald*, intends to equip an expedition for polar exploration.

The Angara.—At its last meeting, February 5, the Section of Physical Geography of the Russian Geographical Society discussed the question of the expedition to be sent for the exploration of the Angara and of the water-divide between the Obi and Yenisei rivers, where, it is expected, a water communication could be established between the two main rivers of Siberia. An elaborate report was read, being a sketch of the present state of our knowledge of these tracts, and of the recent explorations of the water-divide: the route the expedition will have to follow was also discussed.

An Azimuth Instrument.—Capt. Mouchez has presented to the Geographical Society of Paris a portable instrument for taking azimuths and altitudes in travelling. The weight is only a few pounds, and the experiments made at Montsouris show that the latitude can be taken with an error of a few minutes. This instrument is to be used by some travellers that the Paris Geographical Society is sending out to Africa. A single man can carry the apparatus and use it without losing much time. A complete observation requires less than a quarter of an hour.

NOTES

At the meeting of the Linnean Society on Thursday last, it was un[illegible]mously resolved to send a congratulatory letter to von Siebold on the occasion of his jubilee. This graceful act, however, brings into prominence the neglect of the Society to take any notice of the Linnean centenary, the celebration of which in Sweden, Holland, and Germany, were recently noticed in our columns. Of course the excuse may be urged with some force that such formalities are foreign to English habits, but perhaps an exception might have been allowed in the case of a Society which bears the name and jealously guards the collections, books, and manuscripts of the great naturalist. Perhaps, however, another reason may be found in the fact that the constitution of the Society places the initiative in every case in the hands of the officers whose tenure of office is practically indefinite, and who are not very accessible to any impulses of enthusiasm from the general body of the Society even if there were any permissible way by which expression could be given to them. Some disquieting rumours as to the present condition of the Society's business affairs, coupled with its rather troubled history during the past few years, seem to point to the desirability of some changes in its mode of government which would bring the executive into closer relation with the general body of Fellows.

We gave last week a list of the grants just made from the research fund of the Chemical Society; we are glad to state that since making these grants the fund has been increased by the following donations and subscriptions from the "Alkali Manufacturers' Association." The donations, amounting to 220*l.*, are from Messrs. Charles Tennant and Co., 45*l.*; Messrs. J. and L. Pattinson and Co., 35*l.*; Messrs. R. Bealey and Co., 15 Messrs. Roberts, Dale and Co., 5*l.*; Messrs. James Muspratt and Sons, 35*l.*; Mr. A. G. Kurtz, 50*l.*; Mr. Henry Baxter, 25*l.*; Mr. C. J. Schofield, 5*l.*; Mr. Thomas Walker, 9*l.*; Mr. D. McKechnie, 5*l.* The following are the annual subscriptions be continued for five years:—Messrs. Gaskell, Deacon, and Co., 11*l.* 14*s.*; Messrs. Chance Brothers and Co., 4*l.*; The Netham Chemical Company, 4*l.*; W. Pilkington and Son, 7*l.*; Mr. James McBryde and Co., 3*l.*; W. Gossage and Son, 4*l.* 10*s.*; Watson, Kipling, and Co., 2*l.* 18*s.*; amounting altogether to .

The President of the Institute of Chemistry of Great Britain and Ireland offers two prizes of 50*l.* each, to be awarded by the Council of the Institute on February 1, 1879, for the two best original investigations involving gas analysis, and conducted by an associate of the Institute. The investigations must have been made within two years of the date of the award, and must not have been published, if at all, more than six months previous to the award. The prizes will not be awarded unless, in the opinion of the Council, the work is of sufficient merit to qualify the candidate for Fellowship of the Institute.

In his interesting communication on the analogy between chemistry and algebra in our last number, Prof. Sylvester attributes the conception of *valence* or *atomicity* to Kekulé. No doubt the theory in its present developed form owes much both to Kekulé and Cannizaro; indeed, until the latter chemist had placed the atomic weights of the metallic elements upon a consistent basis, the satisfactory development of the doctrine was impossible. The first conception of the theory, however, belongs to Frankland, who first announced it in his paper on Organo-metallic Bodies, read before the Royal Society on June 17, 1852. After referring to the habits of combination of nitrogen, phosphorus, antimony, and arsenic, he says, "It is sufficiently evident, from the examples just given, that such a tendency or law prevails, and that, no matter what the character of the uniting atoms may be, *the combining power of the attracting element*, if I may be allowed the term, *is always satisfied by the same number of these atoms.*" He then proceeds to illustrate this law by the organo-compounds of arsenic, zinc, antimony, tin, and mercury. In conjunction with Kolbe, Frankland was also the first to apply this law to the organic compounds of carbon; their paper on this subject, bearing date December, 1856, having appeared in Liebig's *Annalen* in March, 1857, whilst Kekulé's first memoir, in which he mentions the tetrad functions of carbon, is dated August 15, 1857, and was not published until November 30 in the same year. Kekulé's celebrated paper, however, in which this application of the theory of atomicity to carbon was developed, is dated March 16, 1858, and was published on May 19, 1858. On the other hand, the "chemicographs," or graphic formulæ, which Prof. Sylvester has so successfully applied to algebra, were the invention of Crum Brown, although Frankland has used them to a much greater extent than any other chemist.

At the General Meeting of the Royal Astronomical Society, on February 8th, the Gold Medal was awarded to Baron Dembowski for his double-star measurements.

We learn from the *Diario de Campinas* of the death in that town, on December 20, 1877, of Joaquim Corrêa de Mello, a Brazilian botanist, who was well known as a correspondent to many scientific men in the Old World.

The Rev. Andrew Bloxam, M.A., rector of Harborough Magna, Rugby, formerly incumbent of Twycross, Leicestershire, died on February 2, aged 76. He was well known to British botanists, especially as a diligent student of brambles and roses.

A subscription has been opened at Paris with the view to erect a monument to the late M. Raspail.

Among the exports of Corsica it is said that there are annually between 350,000 and 400,000 blackbirds (*merles*) which are sent to this continent. They visit Corsica in vast numbers each winter to feed on the berries of the myrtle and arbutus, with which the mountains are covered. In the month of December they become very fat, and the flavour and perfume given to their flesh by their food cause them to be much esteemed by the *gourmets* of Paris. A *pâté de foie de merle* is a great delicacy.

Mr. Francis Day writes that in our notice of Dr. Bleeker last week, seven volumes of his "Atlas" are said to have appeared, whereas the first part of volume 9 has been issued to subscribers, and the second part will be shortly. The number of volumes which the work was intended to fill was twelve, the whole of the MSS. for which has been left complete, as well as most of the figures, and we may hope that they may yet be published.

We are glad to learn that Prof. Abich is preparing a complete edition of his numerous and well-known works on the Caucasus, under the title of "Forschungen in Kaukasus-Landern." The first fascicule will contain a new paper on the coal-measures of the middle parts of the Araxus valley, with numerous plates; and the second, a description of the Trialet mountain-range and of its volcanic rocks and mineral waters, with a geological map on a large scale.

Prof. Leuckart has just issued, in Berlin, the first part of his "Bericht uber die wissenschaftlichen Leistungen in der Naturgeschichte der niederen Thiere" for 1872-75, the continuation of the reviews which he has hitherto been accustomed to compile at intervals in this department of zoology.

The Société Centrale d'Apiculture et d'Insectologie has had constructed a pavilion in the Champ de Mars for the purpose of exhibiting in 1878, in the most complete manner, everything relating to the education of useful insects, especially bees, and the means of preservation of all kinds against noxious insects.

Quite recently we had a band of Nubians in London; a small band of Eskimo are at present encamped in Paris, and now, we hear, that shortly Europe will have an opportunity of viewing a group of Aborigines from the opposite side of America. A number of Tierra del Fuegans are to be brought to Brussels, where they will be installed in the Zoological Gardens. The enterprising authorities of the Paris Zoological Gardens contemplate, moreover, importing some specimens of North American Indians, their plan evidently being to keep up a kind of anthropological review of the various civilised and semi-civilised peoples of the globe.

THE German War Department has recently carried out some experiments on a large scale with the electric light at Metz, in order to test its practicability for military purposes. One of the largest known electric lanterns was used for the trials, and it was found possible to distinguish small detachments out of rifle-shot with sufficient accuracy to direct on them artillery fire.

THE alarming rapidity with which shortsightedness is increasing among German students formed the subject of a recent debate in the Prussian Parliament. From extended observations made in the gymnasia, it appears that the number of the shortsighted increases from twenty-three per cent. in the first year to seventy-five per cent. in the ninth or last year. The too-frequent custom in Germany of forcing lads to study during the evenings with insufficient light, in ill-ventilated rooms, is undoubtedly a main cause of this widespread evil.

"HEROES of South African Discovery," by M. D'Anvers, that we referred to in our last number, will be published, we understand, next week by Messrs. Marcus Ward and Co. This volume will contain an account of Stanley's expedition, and the accompanying map will show the route taken by that discoverer.

THE Société d'Hygiene of Paris is making arrangements to establish, in the cities and towns of France, chemical laboratories for the purpose of examining articles of food and detecting adulterations or unhealthful constituents. In this respect France is, like Germany, following the example of England, where the value of public analysts has long since been satisfactorily demonstrated.

WHILE of course the thermo-electric pile is the most useful measuring apparatus in investigations on radiant heat, it is possible, M. Violle suggests (*Journal de Physique*) to repeat easily all fundamental experiments with the radiometer ; by moving it along the spectrum one may readily show (even with the Drummond light) the distribution of the heat in the luminous part and in the infra-red region. The action of coloured glasses, the absorption of heat by water, in layers of different thickness, and all similar phenomena, can be shown without any difficulty. The beam of light employed falls directly, or after passage through the absorbent substance, on the radiometer, the image of which is, by means of a lens, thrown on a screen. The experiment is very distinct and pretty ; it may be rendered more precise by adopting an arrangement for counting the number of turns of the radiometer. M. Violle says he has had constructed by M. Alvergniat a small radiometer for the purpose ; it is placed on a Duboscq projection apparatus ; and the turns can be easily counted on the screen.

IN order to determine the ratio of the specific heats of air at constant pressure and constant volume (a value so important for the doctrine of heat), M. Kayser has recently made fresh experiments on the velocity of sound in tubes. He adopted Kundt's method ; in tubes of different diameter, air waves were produced by means of a transversely vibrating rod, and the length of these was measured by the dust figures remaining on the tube. Five tubes of different width were used, and three different steel rods. The results of the inquiry are these : (1) The velocity of sound in tubes depends on their diameter and on the pitch of the tones, and the retardation of the sound is inversely proportional to the diameter of the tubes, and the square root of the number of vibrations. (2) The velocity of sound in unconfined space is accordingly at any rate greater than in tubes ; these experiments showed it to be greater than 331·646 m. (3) The velocity of sound in free space can be calculated from that in tubes when two tubes of different width are used ; from these experiments the value obtained for it was 332·5 m. (4) From this the ratio of the specific heats of air at constant volume and constant pressure is inferred to be = 1·4106.

THREE experiments, made with a view to find how weak induced currents in the telephone would still suffice to give distinct perceptions by ear, have lately been described to the Vienna Academy by Prof. Sacher, of Salzberg : 1. The closed circuit of the telephone was, for a length of 20 metres, placed parallel with the insulated wire (cloth and wax) of an ordinary telegraph apparatus. The (Morse) signals were given first by means of six, then three, Smee elements. The induced currents gave a distinctly audible effect in the telephone, so that the messages could be understood. 2. The insulated wire was laid bare at two points 20 metres apart, and the ends of a telephone wire 120 metres long, and equally thick, were connected to it at those points. Only a small portion of the current could have passed through the thin wire in the telephone. Yet the tapping was heard with sufficient clearness to enable one to understand the message. (It is an advantage to use a telephone at each ear.) 3. A telephone wire about 40 metres long was connected with the inner thick wire of an ordinary induction coil, and a second telephone line, about 120 m. long, with the outer thin wire. To Prof. Sacher's surprise it was found possible to communicate through the first to the second telephone, and also (somewhat better, it seemed) in the opposite direction ; and this nearly as well as with direct connection. The words were perceived more distinctly when two induction-coils were inserted in the same way. The experiment did not succeed with a Ruhmkorff.

THE improvement of the air-pump, which consisted in dispensing with the flask-like receptacle (with stop-cock) as employed by Otto v. Guericke and Robert Boyle, and introducing the much more convenient plate, is generally attributed to Papin. This is shown by M. Gerland (*Pogg. Ann.*, No. 12, 1878) to be a mistake. In Papin's first paper, "Nouvelles Expériences du Vuide," &c., which appeared in Paris in 1674, and which in 1686 had become rare (the only two copies of it now extant are in possession of the Royal Society, and in the British Museum library), he describes and gives a figure of the machine with which the experiments were made, and says:—"Monsieur Hugens (*sic*) fit faire cette machine, ensuite celle de M. Boyle, et il apporta divers changemens qu'on remarquera en comparant leurs figures." This machine (whose figure M. Gerland reproduces) is the first which has a plate. Additional proof that Huygens has the credit of the device is furnished by a letter of Huygens himself, and the date at which the improvement was introduced is shown to have been 1661.

THE Paris Jardin d'Acclimatation has just received a pair of those peculiar Siberian hares, which are grey in summer and white in winter, for the purpose of studying the effects of a temperate zone on the changes of colour.

THE first telegraph line of the Chinese Empire has recently been established between the arsenal of Tian Tsin and the house of the provincial governor. The constructor was Mr. Betts, the director of the School of Mines of Tian Tsin. Although the line is only some ten kilometres in length yet its construction marks a new epoch in the administration of the Empire. The Great Northern Telegraph Company, in spite of repeated efforts made at Foo Chow, have not succeeded in obtaining the permission of connecting this port with Amoy by a telegraph cable, and after vainly trying for two years have finally given up the idea. The line of Tian Tsin has, however, been constructed by order of the Chinese Government ; and the population offered not the least resistance wherever the telegraph poles were erected. A cable was required for the Pi-ho river, which intersects the line. The apparatus used are Morse's die-writers worked by Leclanché elements. Mr. Betts and some of his assistant pupils have been invited to visit Formosa in order to construct a line on the west coast of this island, viz., between Kee Lung and Tay-wan-foo. It is also proposed to establish another line at Tian Tsin, connecting that city with the capital of the province Paou-ting-foo.

DURING the year 1877 the Parisian press numbered no less than 836 different newspapers and serials (against 754 in 1875). Of these, 51 daily and 14 weekly papers are political, 49 serials are theological (37 Catholic, 10 Protestant, and 2 Israelitic); 66 are dedicated to law, 85 to political economy, 20 to geography, 74 to *belles lettres*; 20 are pedagogic, 52 literary-scientific, 56 artistic, 68 treat of fashions, 77 of technology, 75 of medicine; the contents of 43 are mathematical and natural-scientific, of 22 military, of 31 agricultural. Besides the above there are 16 sporting papers, 13 of various contents, and 4 dedicated to Freemasonry.

MANY alloys of tin and other soft metals hardened by addition of antimony, copper, &c., do not give a clear tone on being struck, but a lead-like, dull one. It has been found by M. Lilliman (*Pol. Notizblatt*) that the power of sounding clearly may be imparted to them, by immersing them for a half to one minute in a paraffin or oil bath, heated to a temperature 5° to 5°·5 below the boiling-point, then taking out and allowing to cool. This does not produce any diminution of density, but a considerable increase of the hardness and rigidity.

THE *Proceedings* of the Bristol Naturalists' Society (vol. ii part 1, new series) contains, as usual, some papers of more than average value. There are three papers on the microscope by Dr. Fripp, two on the Bristol coalfield by Mr. W. W. Stoddart, besides two other geological papers by the same author, a paper by Mr. W. Evans on the scientific aspects of tanning, and other matters of importance. The *Transactions* of the Bedfordshire Natural History Society for 1876-7 contains a number of good papers on local natural history.

THE gasworks at the Grasbrook at Hamburg have recently been covered with a gigantic iron roof, constructed by the "Essener Union." Its weight is 51,500 kilogrammes, its length 84 metres. With the exception of the roof on the Liverpool gasworks, it is the largest in Europe.

AT the meeting of the Royal Academy of Sciences at Berlin, on January 24, Prof. Du Bois Reymond, as President of the Committee of the Humboldt Institution for Naturalists and Travellers, read a detailed report of the activity of this institution during the past year. The first undertaking was that of Herr J. M. Hildebrandt, and referred to the exploration of the snow-clad mountains of Equatorial Africa, viz., of the Mt. Kenia and of the Kilima-Ndjaro. The well-known traveller, although he approached the former mountain to within a few days' march, could not reach it altogether on account of the unconquerable difficulties placed in his way by the enmity of the native tribes, but he will again take up his plan after having recruited his health at home. Herr Hildebrandt, however, has brought home rich scientific collections from his journey, and has presented them to the scientific societies at Berlin; his geological collections are of special interest. The second traveller sent out by the Humboldt Institution, Dr. Karl Sachs, continued and terminated his investigations on the electric eels (*Gymnotus electricus*) at Calabozo, an important town in the Llanos of Venezuela. He succeeded in adding to our knowledge of *Gymnotus* considerably, so that of this species now quite as much is known as of *Torpedo*; he failed, however, to throw any light upon the development of *Gymnotus*. Dr. Sachs is now occupied in writing a treatise on this subject, as well as a description of the country and the people of Venezuela and his own experiences while travelling.

IT is very unsatisfactory to hear that the consignment of soles and turbot which left the Southport Aquarium on January 3 for the purpose of stocking the Bay of Massachussetts has turned out almost a total failure, one pair of the former only having arrived at their destination in safety. Prof. Baird, United States Commissioner of Fish and Fisheries, is so anxious to introduce the above-named fishes into American waters that another journey to England is contemplated about May next. Much experience has been gained in the transit of live fish across the Atlantic, which will be of considerable importance in facilitating future arrangements. It is highly probable that the bony pike and other American fishes, many of which are remarkable for their brilliancy of colour, will ere long find a home in English aquaria.

THE additions to the Zoological Society's Gardens during the past week include a Common Swan (*Cygnus olor*) from Holland, presented by Mr. John Colam, F.Z.S.; two Crested Guinea Fowls (*Numida cristata*) from West Africa, presented by Mr. Collingwood; two Canadian Geese (*Bernicla canadensis*) from North America, presented by Mr. Edward J. Philpot; four Reeves's Terrapins (*Clemmys reevesi*) from China, presented by Mr. A. Thomson; a Brazilian Tortoise (*Testudo tabulata*) from Cartagena, presented by Capt. King; a Poitou Donkey (*Asinus vulgaris*) from the south of France, deposited; an Azara's Fox (*Canis azaræ*) from South America, purchased.

D'ARREST'S SPECTROSCOPICAL RESEARCHES

WHEN the late Prof. d'Arrest was called to superintend the building of the new observatory in Copenhagen and the erection of a large refractor (16 feet focal length by 11 inches aperture), he took advantage of the opportunity thus offered to enter into more extensive researches on the nebulæ, than he had been able to undertake at Leipzig. He intended at first to observe all the nebulæ which were visible in his refractor, but he soon found that a work beyond human power, and that in fact the nebulæ are infinite in number. Working hard for six years he was only able to collect the eighth part of the observations required for laying down approximate positions of all those nebulæ which are distinctly visible in the Copenhagen refractor, and whose places could be exactly determined. These observations were published as "Siderum nebulosorum observationes Havnienses," in 1867, for which the gold medal of the Royal Astronomical Society was awarded to him in 1875. Prof. d'Arrest died eight years after the publication of his great work, his health broken down by constant night-watches. These years were spent mostly on spectroscopical researches, which were partly published in the *Astronomische Nachrichten*, partly in a separate paper, "Undersogelser over de nebulose Stjerner i Henseende til deres spectralanalytiske Egenskaber," in 1872. This latter paper does not appear to be so widely known as it deserves, and an abstract in the columns of NATURE might therefore be acceptable to many.

It took D'Arrest several years to get sufficiently acquainted with the use of the new apparatus—so different from those usually handled by astronomers of the old school. Various forms of spectroscopes are employed according to the subject to be examined. To observe the protuberances or their lines the greatest possible dispersion is required in order to weaken on one hand the sun's light, and on the other hand the diffuse atmospherical light which forms the background on which the lines are projected; while prisms of small dispersive power are employed when for instance the bright lines of comets or nebulæ are examined. D'Arrest's spectroscope was not intended for any extreme application; it was a so-called Janssen's, after Amici's principle composed *à vision directe* of three crown and two flint-glass prisms from Merz.

The solar light has lately been made to go twice through the system of prisms, and the dispersive power thus doubled has rendered many more bright lines visible than were known heretofore. Besides the principal lines C, D$_3$, and F, discovered in 1868, only three or four feeble secondary lines of unusual occurrence were known in the spectrum of the sun's chromosphere, until Prof. Young, in the autumn of 1871, succeeded in raising the number of the visible bright lines to 103 in the course of only four weeks by the above method. These lines are almost uniformly distributed over the whole spectrum from wave-length 706 to 410. The lines are, however, of very varying brightness and frequency. But that artifice is of no good for investigating the planets or planetary nebulæ, for which instruments of the greatest possible amount of light are required.

D'Arrest did not make any profound study of the SUN'S protuberances, but convinced himself of most of the many peculiarities that have been discovered since autumn 1868. He mentions especially the pointed extremities of C and D$_3$, and the broad basis and *fine point* of F. This is explained by a lowering of temperature and density at a distance from the sun's surface, but it is certain that this phenomenon, with its physical consequences, appears with very different intensity by C and by F, from what it does by Hα and Hβ of hydrogen. It appears remarkably enough most distinctly by the feeblest of the two. The lines Hγ and Hδ are in themselves far more insignificant, and their extension no doubt smaller. D$_3$ is of another unknown origin. He often observed, besides, the oblique position and distortion of the F-line in protuberances, which were evidently produced by violent eruptions, but he never saw distortions so violent that the line shoots branches to both sides, and at last is altogether dilacerated. Lockyer has represented many such cases in vol. xviii. of the *Proceedings* of the Royal Society. Secchi does not mention them in his book on the sun (Paris, 1871), and they have perhaps only been seen by Young besides. As to the explanation, we meet with a difficulty similar to that above; the phenomenon shows itself principally and nearly exclusively in this single line. D'Arrest never noticed such a thing in Hα. It is explained by the rapidly rotating mass of hydrogen towards or from the slit of the spectroscope, the wave-length of the light being thus alternately lessened and increased. He calculated a velocity of fifty or sixty geographical miles in the second from the greatest displacement he noticed by the F-line. The direct consideration of the occasional explosive alterations of protuberances leads to similar conclusions. It is beyond doubt that the velocity is so enormous. Much smaller displacements could besides hardly be ascertained by means of the spectroscope.

The spectra of the *sun-spots* have been examined ably by different investigators, and a rich material exists which shows the most probable assumption to be that the sun-spots are the results of cooling. It is in fair accordance with this interpretation that the increased absorption of light which the spot-spectrum shows by augmentation of the lines in breadth and darkness is considered a proof of the condensation of the gases, to whose absorption the dark lines in the normal sun-spectrum owe their origin. According to d'Arrest's opinion, this pervading *élargissement* must be mainly attributed to the circumstance that the lines are seen on a darker background where the irradiation is greatly lessened, and he believes that the whole theory, which is founded on the supposition of elective absorption of the spots is not quite to be trusted as yet. He never saw bright lines in any spot-spectrum, and mentions that other assiduous observers have likewise failed in this respect. The normal dark lines in the sun-spectrum are of very different degrees of darkness and breadth; some exhibit sharp borders, while others are winged, &c. These intrinsic relations he remarked did not change in the spot-spectra from what they were in the neighbouring region. He found, for instance D$_2$ to enlarge more than D$_1$ in proportion to their different breadths in the normal spectrum. From the lessened irradiation, moreover, some sharp lines of the normal-spectrum may become somewhat foggy in the spot-spectrum, as Secchi (*Compt. Rend.* 1869, p. 520) states is the case with the principal lines of sodium, a circumstance which, however, d'Arrest did not confirm any more than the remark by the same astronomer that the lines of magnesium are hardly enlarged in the spot-spectrum. Lockyer says (*Proceedings*, Royal Society, vol. xvii. p. 352) that they are thicker when observed in a spot than usual. Vogel has remarked a similar thickening of easily visible dark lines in Jupiter's spectrum in those parts of the spectrum which correspond to the dark bands on the planetary disk.

D'Arrest does not consider his observations as sufficient to establish anything as to the encroachment of the gas lines in the spot-spectra which occasionally has been observed by the so-called light-bridges in the interior of the spots; he remarks that a similar phenomenon may be produced spontaneously by looking at the image of one of the gas-lines of the protuberances, when the slit is not placed exactly in accordance to the refrangibility of this particular line, and investigators may not have been sufficiently attentive to this circumstance. The light concentrated in the few protuberance-lines is of course stronger than the light of the continuous spectrum of the border, and when the slit is even very slightly displaced the protuberances appear distinctly to reach within it. The same is the case with protuberances inside on the disc of the sun, where they mainly betray themselves by partial reversal of some lines from dark to bright.

The whole of astronomical spectrum analysis is founded upon the law that the source of the light of a continuous (with or without dark lines) spectrum containing rays of every refrangibility, is a solid or fluid substance, and that the source is a glowing gas whenever the spectrum is discontinuous and reduced to separate bright lines. This must within certain limits of pressure be considered as raised beyond doubt, although most skilful chemists disagree as to the nature of spectra of different orders. Plücker and Wüllner state that the same substance gives different spectra at different pressures and temperatures. Dubrunfaut, Reitlinger, and, above all, Angström deny this. The special use which has been made of Geissler's tubes in astronomical observatories is at any rate rather doubtful, since chemists have shown the true nature of the compound spectra which such tubes may furnish—for instance of hydrogen and nitrogen.

Dr. Huggins examined for the first time on August 29, 1864, one of the brightest planetary nebulæ (H., iv. 37) and found the spectrum concentrated in three short bright lines. This discovery proved the nebula to consist of glowing gas under a feeble pressure. Thus also for the first time was obtained the means of distinguishing between true nebulæ and conglomerations of stars. The latter, by far the most common, show the continuous spectrum, the former the linear. This question would hardly ever have been definitely answered by aid of any telescope. First Huggins, then Rosse and Secchi examined almost all those nebulæ in the northern sky, which were visible in their apparatus, and only one or two observers have since made further investigations on the single objects. Capt. J. Herschel examined (1868) in India the southern nebulæ spectroscopically. Most gaseous nebulæ are planetary. D'Arrest had already in his smaller catalogue in 1855 remarked about H. iv. 18: "bluish quiet light, as all planetary nebulæ seen by me show it," and in 1866 in "Obs. Havn." about H. iv. 37:—"Unica prope inter nebulas et prorsus singularis. Ellipsis est egregie cærulea cet." We now know both these to be gaseous nebulæ, analysis showing the light concentrated into three lines near each other in the green and blue regions of the spectrum.

The exact determination of the place of the lines in the normal spectrum was connected with great difficulties on account of their feeble light. It was therefore at first uncertain whether the three lines were identical in the different spectra, but there can now be no doubt as to this, and d'Arrest found by a discussion of the observations of Capt. Herschel, Secchi, and especially Vogel the following wave-lengths for the lines. The line Neb. (3) has by Huggins and Miller, Secchi, and lately Vogel, been proved to coincide with the F-line (Hβ) and d'Arrest assumes in consequence its wave-length after Angstrom:—

	Wave-length.	Vibrations in 1 second.
Neb. (1)	500·40 mill. millim.	596·64 billions.
Neb. (2)	495·00 ,, ,,	602·35 ,,
Neb. (3)	486·00 ,, ,,	614·25 ,,

Beyond Neb. (3) is occasionally (by H. iv. 18 and the Orion nebula) perceived a fourth line Hγ, but it is very difficult to see it.

The spectra of the different objects are, however, very unlike each other on account of the different *intensities* of the bright lines. There is even occasion to presume that the *mixed gas spectra* do not ever continue unchanged with regard to the relative intensity of the lines, which is very likely, as the relative brilliancy of both the green lines of glowing H and N depends upon the mixture of the gases.

We know that air when under a feeble pressure heated by an induction-current, exhibits the line Neb. (1); it belongs to *nitrogen*.[1] Lockyer and Frankland (*Proceedings*, Royal Society, vol. xvii. p. 454) have shown that the in reality very complicated spectrum of nitrogen, under certain circumstances of pressure and temperature, [illegible]educed to this bright line with but feeble traces of the others. It is, besides, the brightest of them all. Extensive investigations published on this subject cannot, however, be said fully to elucidate the question why the other lines of nitrogen do not appear in the spectrum, nor do physicists agree as to the temperature and density which, under these circumstances, must be supposed in the nebulæ. It is, besides, precarious to draw from phenomena observed in Geissler's tubes conclusions as to circumstances prevailing in the vast nebulæ (Zollner, *Berichte der k. sachsischen Gesellschaft d. Wissensch*, for 1870, p. 254). It appears less important that nobody has been able to comply with Angstrom's demand when he says ("Recherches sur le Spectre solaire," p. 37) :—"This line is double. . . . It appears, therefore, that we ought to be able to show this duplicity in the corresponding line of the nebular spectrum." To their separation is required too narrow a slit for the feeble light of the nebulæ. All considered, nitrogen is at present very likely one of the constituents of nebulæ.

---

[1] D'Arrest mentions that the above wave-length agrees perfectly with Huggins's observation, when he identifies Neb. (1), not with the middle of the double line, but with the least refrangible of the two.

The origin of *Neb.* (2) is not known. The idea at first occurred to Huggins of one of the many barium-lines, but he soon gave this idea up. One of the iron lines holds exactly its place ; it is a dark line, but not one of the principal of the rich spectrum ; of course this coincidence is accidental. This line is again met with in the spectrum of many red and variable stars. The measures of Vogel (*Ber. d. k. sachs. Gesellsch. d. Wissensch.*, 1871, December 17) agree well enough with the gaseous line when the great difficulties of the cases are taken into account. *Neb.* (2) does *not* occur in the spectra of comets.

Neb. (3) is identical with the line $H\beta$ of hydrogen, whose existence in gaseous nebulæ was proved when Huggins discovered Neb. (4), which is $H\gamma$, that was so long sought for in vain. Hydrogen is everywhere found as one of the constituents of the heavenly bodies, but the comets contain no traces of it. The hydrogen-lines appear even in the spectra of many fixed stars, at least through $H\alpha$ and $H\beta$, but sometimes $H\beta$ and $H\gamma$ are the strongest (β Lyræ), and three hydrogen lines are distinctly seen in the spectra of α Aquilæ and α Lyræ.

D'Arrest then gives in his paper a list of all the nebulæ which have been spectroscopically examined by himself or others.

He speaks first of the gaseous nebulæ, of which H. iv. 37 is the most remarkable ; then he mentions those whose spectra are continuous, and thus proved to be mere conglomerates of stars. The latter are by far the most difficult to examine, the feeble light being distributed over a large space, and generally minima visibilia. An astronomer well versed in the use of the spectroscope is, however, often able to decide whether the spectrum is continuous, even if it be not visible by glimpses. Already the absence of the spectrum may occasionally hint about the true nature of the body. He estimates the number of nebulæ known in the middle of 1872 to be about 6,000 ; of these 150 have been examined with the spectroscope. It is, therefore, only the fortieth part, which is bright enough to be seen through the system of prisms. Although it is hardly possible to draw conclusions from so small a fraction of the whole, still d'Arrest thinks it possible, on account of the critical revision he has given the observations, to arrive by induction at a few results. He finds that of a given number of nebulæ about a fourth give the discontinuous spectrum, while three-fourths give the

Gas nebulæ are, with but few exceptions, known by their green-blue light, their sharply-defined, round, or elliptic discs with annular bright condensations inside. There are, however, large, extensive, irregular, and complicated nebulæ, which also consist of the three gases, nitrogen ever foremost, though the gases are mixed in different proportions. The very feeble continuous spectrum which appears in many planetary nebulæ can in most cases be shown to arise from the consolidated nucleus, the fluid or solid central mass. The distribution of brightness in extensive nebulosities is very irregular, and the heat in certain regions rises and falls occasionally a little, though no real alterations in the form are known as yet.

The ray-nebulæ are surely mere conglomerations of stars. Those are the long, lenticular nebulæ, often so narrow and fine that such an object may resemble a thin bright line drawn through the nucleus. No such nebula is hitherto known to give a tri-chromatic spectrum.

It was in 1866 that Secchi commenced to examine red stars with remarkable broad bands in the spectra, and he was already, in 1868, compelled to add a fourth class to his three classes of star-spectra. A systematical search after remarkable star-spectra was undertaken in 1873 and following years in Copenhagen. D'Arrest's four papers in *Astronomische Nachrichten* contain only the most remarkable of those he found, and only such as had not previously been mentioned. That most are above the eighth magnitude is evidently only founded on the difficulty of seeing spectra of smaller stars.

The circumstance which Secchi remarked in 1868, that yellow and red colours are so often connected with prominent spectra, seems certainly to be of importance, but the many exceptions should warn us from here expecting any great cosmical law. Neither is their connection with variability a rule without exceptions. There are many strongly coloured stars with very indifferent spectra.

Most of the spectra described are of the third class. These are not uncommon, for when we examine 140 stars we may expect to find one of the third class. They are uniformly distributed over the sky, and found also by white stars. The character of spectra of this class is constant throughout. The positions of the dark bands were also shown by Vogel, in 1872, to be the same for four bright stars. The columns are generally more distinctly separated towards the red end of the spectrum, though the contrary occurs also, and it is even possible to follow the steps from but finely-indicated bands to absolute discontinuity, but the colour has nothing to do with these gradations.

Still more intimately connected with orange colour is the fourth class, and specimens of this class are, in consequence, very uncommon. D'Arrest ascertained that the dark bands in the star-spectra are formed by groups of compressed dark lines against Secchi's experience. He examined spectra of stars with great proper motion, and found, for instance, the spectra of 61 Cygni and 1830 Groomb. to be indifferent, uniform, and continuous. General similarity of the spectra in certain parts of the sky does not exist at all, or has not been proved yet ; for instance, it is not true that red and yellow are wanting in the spectra of small stars in Orion.

W. D.

THE PROGRESS OF METEOROLOGY[1]

AT the opening of his address Dr. Neumayer regretted that the general knowledge and public appreciation of meteorology was still very small in comparison with that of other branches of science. The main object of his address was therefore to induce his hearers to do all in their power to effect a more perfect and detailed understanding of this branch of science among their countrymen in their respective spheres of activity. He treated the subject, and particularly the weather-forecasts, mainly from his own point of view as a naval officer, and pointed out how desirable a greater interest in marine affairs would be in all circles of German home life. The course which meteorology in its application to daily life has taken may be divided into two categories of observations, first the uninterrupted systematic meteorological investigations, and second, the atmospheric disturbances or phenomena governed by the laws of winds, as first described some fifty years ago by Prof. Dove. He then gave a sketch of the progress of meteorology in other countries ; of the establishment of the numerous meteorological stations, and the application of telegraphy to this science ; of the enormous help afforded by the introduction of rapid means of communication. He pointed out how the greatest progress was made by the United States of North America ; that England was second in this respect, and was followed by Holland, France, and Denmark. According to the latest news, the yearly budget for meteorological observations in the United States was raised from 250,000 to 450,000 dollars, apart from all personal expenses. The rise in this sum is explained by the necessity of having special telegraph wires and stations solely for the meteorological service and by the increase in the staff of observers. If in Europe the practical results of observations are not quite as satisfactory as might be desired, it is because the European organization of the meteorological service is far more imperfect than the American one. The German Government has given its full attention to this important science, particularly with regard to the German navy and the coast population. The poor German fishermen in the Baltic and the German Ocean are already deriving great benefit from the numerous meteorological stations which have been established along the German coast-line, although it is only eighteen months since the service has begun. The German "Seewarte" has been established and now performs its share of international work along with the sister-establishments of England, Holland, and France. Agriculturists will

[1] Meteorology in Daily Life. Address delivered at the meeting of the German Aſsociation at Munich, by Dr. G. Neumayer, Director of the Deutsche Seewarte at Hamburg.

derive equal benefit from the meteorological service if inland stations are established and care is taken that the general population of the country are taught how to appreciate their work. Dr. Neumayer concluded with the sentence :—It is not only the duty of the State to found beneficial institutions and to organise them efficiently, it is also the duty of the State-citizen to learn to understand and to appreciate these institutions and to enter into this spirit of the work they are called upon to perform.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

St. Andrew's.—The Senatus Academicus of St. Andrew's University have conferred the degree of LL.D. upon Mr. Henry Woodward, F.R.S., of the British Museum, and Dr. W. C. Macintosh, of Murthly, well known for his researches on British annelides.

The Yorkshire College, Leeds.—Mr. Arnold Lupton, F.G.S., has been elected Instructor of Coal Mining, a department recently endowed by the Drapers' Company of London.

Higher Education of Women.—A public meeting composed for the most part of ladies, was held on the 6th instant in the Vestry Hall, Kensington, to inaugurate the system of lectures for the higher education of women, undertaken by the Principal and Professors of King's College with the co-operation of the Women's Educational Union. The object of the lectures, which commenced on the 11th instant, is to supplement and continue school education, and the instruction will have, as far as possible, reference to the examinations open to women in the University of London or elsewhere. The minimum age of students is fixed at 17, except in such cases as receive the special sanction of the committee. The classes will be at present held in the Vestry-hall, High Street, Kensington. The curriculum embraces Holy Scripture and Church history, logic and moral philosophy, modern and ancient history, the English, Latin, French, and German languages and literatures, mathematics, mechanics, and botany. Experimental physics, chemistry, and drawing will also be taught as soon as suitable arrangements can be made. Other classes, if necessary, will also be formed. The fees vary from 10*s.* 6*d.* to 2*l.* 2*s.* per term ; for any four complete courses they will 6*l.* 6*s.* For ladies engaged in teaching there will be a remission of 25 per cent.

Prizes in Botany for Young Women.—The Society of Apothecaries of London announce their intention to award prizes to young women students in botany for proficiency in that science, the prizes to be competed for under the following conditions :—The competition will be open to all young women who shall produce from their teachers certificates that their age at the time of examination does not exceed twenty years. The examination will be in general and not medical botany. It will consist of questions both written and oral, in—(1) Structural Botany ; (2) Vegetable Physiology ; (3) Description of Living Plants ; (4) Systematic Botany ; so far as these subjects are contained in Sir Joseph Hooker's "Science Primer—Botany," and in Prof. Oliver's "Lessons in Elementary Botany." The first examination will take place in London on the third Wednesday and the third Friday in June, 1878. Candidates will be required to send their names and their residences, at least fourteen days before the examination, to the Beadle, Apothecaries' Hall, Blackfriars, E.C., when they will receive tickets of admission to the examination.

France.—M. Bardoux, the French Minister of Public Instruction has taken preliminary steps for organising at Paris on the occasion of the Universal Exhibition, a great congress of schoolmasters. A delegate from each district will be sent by his fellow-teachers. Not less than 4,000 are expected to be present. M. Bardoux has again taken up in the French Chamber the proposed erection of new schools in France. M. Waddington was the originator of the scheme. It is intended to build no less than 17,320 new school-houses, and purchase, enlarge, or restore 12,000 others.

SCIENTIFIC SERIALS

Verhandlungen der k.k. zoologisch-botanischen Gesellschaft in Wien (vol. i., 1877).—This volume contains the continuations of, and additions to, several important papers commenced in the volumes for previous years. We mention particularly the mycological researches by Herr Schulzer von Müggenburg.—The other papers, of which some are very elaborate, are :—On *Cecidomyidæ*, by Dr. Franz Löw.—On the Diptera genus *Medeterus*, Fischer, by F. Kowarz.—On the fungus flora of Vienna, by W. Voss.—On some spiders from Madagascar, by Count E. Keyserling.—On some American spider genera from the families *Pholcoidæ*, *Scytodoidæ*, and *Dysderoidæ*, by the same.—On the *Holothuria* fauna of the Mediterranean, by Dr. Emil von Marenzeller.—On *Psyllodæ*, by Dr. Franz Löw.—On the *Chalcidiæ* genus *Olinx*, by Dr. Gustav Mayr.—Coleopterum, species novae, by E. Reitter.—On the passage of *Pastor roseus* (Temm.) through Austria, Hungary, and the neighbouring countries in 1875, by V. von Tschusi.—Ornithological notes, by B. P. Hanf.—On the flora of Southern Istria, by I. Freyn.—On the lepidoptera fauna of the Dolomite district, by I. Mann and A. Rogenhofer.—On the coleoptera fauna of Central Africa, by P. V. Gredler.—The volume concludes with an interesting description of the piscicultural establishment of Herr A. Fruwirth at Freiland, near St. Polten (Lower Austria), by Dr. E. von Marenzeller.

Memorie della Società degli Spettroscopisti Italiani, May, 1877.—A note on the solar eruptions during 1876, by Prof. Tacchini. Number of days of observation, 106 ; number of eruptions, 9, two on eastern limb and 7 on western limb.—Note by the same author on the present solar phenomena as compared with those during the maximum spot period ; the number of eruptions observed at Palermo in 1871 were 97, while only one was seen in the first four months of this year. Letter from Father Secchi to Prof. Tacchini on the above subject, also a letter between the same persons relative to Winnecke's comet Drawings of solar prominences for January and February, 1876, accompany this number.

June.—Note on a water-prism, by Father Secchi. Path of solar protuberance observed at Rome in April, 1877 ; same for May. Note by Prof. Tacchini, on a metallic solar eruption seen in June last ; the following lines were visible in the spectrum : b^1, E, b^3, b^4, 1474*k*, 4923*A*, 5017*A*, sodium, 5369.*A*.

July.—Continuation of the above note.—Note by Prof. Millosevich, on the contact of Mercury with the sun's chromosphere on May 6, 1878.—Drawings of the chromosphere for the months of March, April, and May, 1876, accompany this number.

August.—Note on the zodiacal light, by Prof. Serpieri. Announcement of the death of Eduardo Heis.—Description of a new form of gravity escapement, by Prof. Young.—The spectroscopic drawings of the chromosphere for June and July, 1876, accompany this number.

September.—A paper on the discovery of oxygen in the sun by photography, and a new theory of the solar spectrum, by Prof. H. Draper. [This discovery, and all matter relating thereto, have already been fully reported in our columns.]—Table of solar protuberances observed at Rome in June, 1877.—Table of solar spots seen at Palermo in July and August, 1877. Four maps, together with a preface by Prof. Heis explaining them ; the maps are of a portion of the heavens adjoining the ecliptic, and show stars down to the fifth magnitude, and they are for use in determining the position of the zodiacal light.

Journal de Physique, January.—On the employment of rotating discs for the study of coloured luminous sensations, by M. Rosenstiehl.—On the use of the radiometer as an apparatus of demonstration, by M. Violle.—Rheostatic machine, by M. Planté.—Experimental researches on the interferences of light, by M. Righi.

SOCIETIES AND ACADEMIES

London

Royal Society, January 10.—"On the Structure and Development of the Skull in the Common Snake (*Tropidonotus natrix*)," by W. K. Parker, F.R.S.

"Observations on the Nervous System of *Aurelia aurita*," by Edward Albert Schafer, Assistant-Professor of Physiology in University College, London. Communicated by W. Sharpey, M.D., LL.D., F.R.S.

January 24.—"The Cortical Lamination of the Motor Area of the Brain," by [illegible]van Lewis, F.R.M.S., Pathologist and Assist Med. Officer to the West Riding Asylum, and Henry Clarke, L.R.C.P. Lond., Med. Officer to the West Riding Prison.

Communicated by D. Ferrier, M.A., M.D., F.R.S., Professor of Forensic Medicine, King's College, London.

January 31.—"Further Researches on the Minute Structure of the Thyroid Gland." Preliminary Communication. By E Cresswell Baber, M.B. Lond. Communicated by Dr. Klein, F.R.S.

"On the Limits to the Order and Degree to the Fundamental Invariants of Binary Quantics," by J. J. Sylvester, M.A., LL.D., F.R.S., Professor in the Johns Hopkins University, Baltimore, U.S.

"Remarks connected with the Number of Figures in the Periods of the Reciprocals of Prime Numbers," by William Shanks, communicated by Rev. Dr. Salmon, F.R.S.

Linnean Society, January 17.—Prof. Allman, president, in the chair.—Specimens of Dipterocarpaceæ collected by Signor Beccari, in New Guinea, were exhibited and commented on by Mr. Thiselton Dyer.—Attention was drawn by Mr. E. M. Holmes to a Japanese book containing sections of native woods botanically named in English, Latin, and Japanese.—Several examples of fasciated stems of the Fuller's Teazel (*Dipsacus fullorum*) were exhibited by Mr. J. R. Jackson, who stated these curiously malformed stems were now successfully introduced for the handles of sunshades; he also made remarks on a bird's nest formed of wool and cotton-pod, sent by Sir Bartle Frere to the Kew Museum.—Prof. Owen then read a paper on *Hypsiprymnodon*, a genus indicative of a distinct family in the Diprotodont section of the marsupials. The animal in question is an inhabitant of the Rockingham Bay district, Queensland, and sparingly frequents the dense, damp scrubs bordering the coast. It is diurnal, and feeds on insects, worms, and tuberous roots, or palm berries, holding these in its fore-paws, and sitting on its haunches, after the manner of the phalangers. They breed during the rainy season, February to May. Both sexes have a musky odour, are nearly alike in size, and somewhat over a foot long. This Rat Kangaroo (*H. moschatus*) Mr. Ramsay, of Sydney, first named and gave a short description of, and Prof. Owen now supplements by a fuller account of its skeleton, &c. Besides peculiarities in dentition and skull, the latter dwells on the structural conditions of the hind foot, a modification between that of the Potoroos and Kangaroos. He thereafter enters into comparisons with the feet of the ostrich group (*Struthionidæ*), and speculates on the modifications of the five-toed feet revealed by palæontology, and as applicable to the living marsupials &c. —Mr. Francis Darwin's communication, experiments on the nutrition of *Drosera rotundifolia*, we gave an abstract of in NATURE, vol. xvi. p. 222.—Notes touching recent researches on the Radiolaria, was the title of a paper by Prof. St. G. Mivart. In this *résumé* the history, progress, and present condition of the subject are elucidated. These remarkable marine surface-swimming organisms the author proposes to arrange after the classification adopted by Prof. Haeckel, but considerably modified. The primary groups are reduced from fifteen to seven as follows:—1. Discida; 2. Flagellifera; 3. Entosphorida; 4. Acanthometrida: 5. Polycistina; 6. Collozoa; and 7. Vesiculata.—Mr. J. Kerswill was elected a Fellow of the Society.

Anthropological Institute, January 29.—Mr. John Evans, D.C.L., F.R.S., president, in the chair.—Anniversary Meeting. —The president, in the course of his address, alluded to the late conference on the "Antiquity of Man," and expressed his opinion that the question might be discussed with as great advantage from a purely English point of view, as from one embracing a larger area, which to some extent held good with regard to the question as to whether the palæolithic implements of the river-gravel might not be referred to an interglacial period. As to the relics of human workmanship thought to have been discovered in beds of pliocene and even miocene age in Italy, Switzerland, and France, Mr. Evans again on this occasion repeated the words of caution he had previously expressed, but nevertheless believed that eventually traces of man would be found of an earlier date than that which can be assigned either to the cave or river-gravels of Western Europe. These traces were to be rather looked for in the east than in the temperate west or colder north. A strong hope was expressed that Indian geologists would ere long solve in a satisfactory manner the date and origin of the so-called laterite deposits of Madras, but Mr. Evans was able to announce that in Borneo there appeared a chance of some cave explorations being carried on which will probably throw light on the date of man's appearance in that part of the globe. Mr. Everitt, whose experience in cave explorations is well known, has proposed to devote a year to further researches, and Mr. Evans having guaranteed the necessary funds appealed to all those who were interested in the early history of man or in palæontology to assist in raising the by no means inconsiderable amount. The following are the council elected to serve for the ensuing year:—President, John Evans, D.C.L., F.R.S.; Vice-presidents, Prof. George Busk, F.R.S., Hyde Clarke, Major-General A. Lane Fox, F.R.S., Francis Galton, F.R.S., Sir J. Lubbock, Bart., M.P., D.C.L., F.R.S., Prof. Rolleston, M.D., F.R.S.; Directors and Hon. Secs., E. W. Brabrook, F.S.A., W. L. Distant, J. E. Price, F.S.A.; Treasurer, F. G. Hilton Price, F.G.S.; Council, J. Beddoe, M.D., F.R.S., James Bonwick, F.R.G.S., C. H. E. Carmichael, M.A., J. Barnard Davis, M.D., F.R.S., W. Boyd Dawkins, F.R.S., Capt. Harold Dillon, F.S.A., Prof. W. H. Flower, F.R.S., A. W. Franks, M.A., F.R.S., Charles Harrison, F.S.A., J. Park Harrison, M.A., Prof. Huxley, F.R.S., A. L. Lewis, R. Biddulph Martin, F. W. Rudler, F.G.S., C. R. Des Ruffières, F.R.S.L., Lord Arthur Russell, M.P., Rev. Prof. Sayce, M.A., M.R.A.S., E. Burnet Tylor, D.C.L., C. Staniland Wake, M. J. Walhouse, F.R.A.S.

Physical Society, February 2.—Annual General Meeting. —Prof. G. C. Foster, president, in the chair.—The president read the report of the Council for the past year. After pointing with satisfaction to the present condition of the Society, the report goes on to show how it is hoped to extend its usefulness in the future. In addition to a second edition of Prof. Everett's work on the C. G. S. system of units, the Council hopes very shortly to publish Sir Charles Wheatstone's papers in a collected form, and it is making arrangements for the publication, at intervals, of translations of foreign scientific papers, especially such as have had a marked effect on the progress of physical science. A portion of the funds of the Society is to be devoted annually to the formation of a library, and an exchange of publications is already made with various learned societies abroad. Special stress was laid on the distinctive object held in view at the formation of the Society, namely the exhibition, when practicable, of the experiments referred to in papers read at the meetings.—The following officers and council were elected for the ensuing year:—President, Prof. W. G. Adams, M.A., F.R.S.; Vice-presidents (who have filled the office of president), Dr. J. H. Gladstone, F.R.S., and Prof. G. C. Foster, F.R.S.; Vice-presidents, Prof. R. B. Clifton, M.A., F.R.S., W. Spottiswoode, LL.D., F.R.S; W. H. Stone, M.B., F.R.C.P., Sir W. Thomson, LL.D. F.R.S.; Secretaries, Prof. A. W. Reinold, M.A., W. Chandler, Roberts, F.R.S.; Treasurer, Dr. E. Atkinson; Demonstrator, Prof. F. Guthrie, Ph.D., F.R.S.; other Members of Council, Capt. W. de W. Abney, R.E., F.R.S., Prof. W. F. Barrett, F.R.S.E., Major E. R. Festing, R.E., W. Huggins, D.C.L. F.R.S., Prof. A. B. W. Kennedy, C.E., O. J. Lodge, D.Sc., Prof. H. M. McLeod, the Earl of Rosse, D.C.L., F.R.S., Prof. W. C. Unwin, B.Sc., R. Wormell, D.Sc. Prof. H. L. F. Helmholtz and Prof. W. E. Weber were elected Honorary Members of the Society. After votes of thanks had been passed to the Lords of the Committee of Council on Education for the use of the physical lecture room at South Kensington, as well as for the other advantages enjoyed by the Society, and to the several officers of the Society, the meeting was resolved into an ordinary one. The following candidates were elected Members of the Society:—M. T. Cormack, C. J. Faulkner, M.A., E. M. Jones, F.R.A.S., C. Leudesdorf, M.A., and C. E. Walduck.—Prof. S. P. Thompson exhibited a method of showing the lines of force due to two currents of electricity running in parallel directions. A plate of glass is perforated by two holes close together, which are traversed by one and the same wire, and this may be so arranged that the current traverses the parallel lengths in the same or opposite directions. If now the plate be held horizontally while the current passes, and fine iron filings be sprinkled on the plate, they will arrange themselves in the well-known forms. In the plates exhibited the filings had been fixed by gum, so that their arrangement could be exhibited to an audience by projection on a screen.

Chemical Society, February 7.—Dr. Gladstone, president, in the chair.—The following papers were read:—The alkaloids of the aconites, Part II.—On the alkaloids contained in *Aconitum ferox*, by Dr. Wright and Mr. Luff. The alkaloid pseudaconitin from *Aconitum ferox* forms crystallised salts with difficulty. Aconitin, from *A. napellus*, on the other hand, crystallises with facility. When acted upon by saponifying agents, pseudaconitin is converted into dimethylprotocatechnic acid, and a new base, pseudaconin; mineral acids saponify pseudaconitin; tartaric acid forms the anhydro-derivative apopseudaconitin. With glacial acetic, and benzoic acids an acetyl and a benzoyl derivative are respectively formed. The properties, constitution, &c., of the above substances have been investigated by the authors. The nitrate and the gold salt of pseudaconitin were obtained in the crystalline form.—Notes on the tannins, by Dr. Paul and Mr. Kingzett. The authors conclude that (*a*) the supposition that natural tannin from gall-nuts is a glucoside is doubtful, (*b*) the astringent principle common to cutch and extract of mimosa bark is shown to be a glucoside and to yield on decomposition, unfermentable sugar and a peculiar acid distinct from gallic acid.—On the estimation of phosphorus in iron and steel. by E. Riley. The author has instituted a series of experiments as to the relative value of the molybdate and magnesia processes for determining phosphorus; as a general result, he concludes that the molybdate process always gives results which are too low, and that the magnesia method is the only one to be trusted.—An inquiry into the action of the copper-zinc couple on alkaline oxy-salts, by Dr. Gladstone and Mr. Tribe. The action of the couple on these oxy-salts is of an electrolytic nature; nitrites and ammonia are at first formed, but ammonia is the final product, when nitrates are taken: chlorides are formed, when chlorates are decomposed, but no chlorites or hypochlorites could be detected. When ammonium nitrate is acted on at the boiling-point nitric oxide is evolved.—On a new method for the determination of boiling-points, by H. C. Jones. A glass tube 4 mm. internal diameter and 200 mm. long is bent into a U, so that the one end, which is open, projects 15 mm. beyond the other which is closed. The closed leg is filled completely, and the open leg partly, with mercury, and a bubble of liquid manipulated into the closed end of the U. On immersing the U in a paraffin path and heating the latter, the liquid boils and the temperature at which the levels of the mercury in the two limbs are equal is the uncorrected boiling-point of the liquid.

THE HEAD-MASTERS ON SCIENCE TEACHING[1]

It is much to the credit of the head-masters that they should have moved voluntarily in the matter of science teaching. The great majority of them are known to look upon it without hostility, but have hesitated to introduce it into their schools, in ignorance of its educational value, of the time and teaching power necessary, of subjects, methods, cost. Since the Report of the Science Commission all see that it must come, and that it is better for the schools to shape the system to be adopted leisurely and in concert than to wait till it is forced upon them from without. A few schools have already accepted it in principle; a very few have worked it adequately for some years past; to these the Head-Masters' Committee have applied for information, and their published answers are before us.

Questions were issued to the masters of twenty-four schools, of whom nineteen replied. They refer to the time spent on science in actual school work, the percentage of boys taught, the age at which teaching should begin, the subjects included, the methods and texts employed, the intellectual results apparent, the value of laboratory work, the cost of appliances, the influence, good and evil, of university scholarships, the text-books recommended; and it was requested that the answers might convey not individual theories of what might and ought to be, but a record of what had been and was being done in each particular school.

It is evident that the first question, as to time spent in teaching, is vital to the whole, and should determine primarily the comparative weight due to the answers sent from each head-master. Unfortunately the answers to it are in a great measure unreliable. Only one school gives the total number of its actual working hours; some do, and some do not apparently include hours of "preparation" in their estimate; one large school, Clifton, omits to reckon the extra time given to special classes, and probably others do the same; while Harrow, Magdalen, and Dulwich, all valuable witnesses, make no return. Taking the answers as they stand, eleven of the nineteen schools give from two to four hours only as a maximum per week, inclusive of practical work; and in some cases, at least, this is probably correct, representing also many more schools than are included in the list. Such schools have made a good beginning, are feeling their way to more extended teaching, and will hail the information given in these pages. But their maximum would be thought ludicrous in the case of literature or mathematics; it gives no real chance to science either as a storehouse of useful knowledge, or as a weapon of intellectual training; and accordingly the evidence valuable to schoolmasters is contained mainly in the answers sent by the remaining schools.

These may be tabulated as follows:—

School.	Hours per week given to science in different parts of school.	Percentage of boys learning science.
Bradford	10, 4, 3, 2	No return.
Clifton[1]	10, 4	90
Giggleswick	8, 6, 5, 2	80
King's College ..	7, 5, 5	No return.
Manchester	12, 9, 3½	No return.
Newcastle-under-Lyme	7, 4, 2	90
Taunton	10, 8, 4, 3	87
Wellington	6, 3½, ½	73

As regards the age at which the study should commence, Clifton, Taunton, and Wellington think that it cannot begin too early; the rest give years ranging from ten to thirteen. All the schools agree in teaching chemistry and physics; three teach botany, three geology. All test progress by periodical frequent examinations within the school, Clifton and Taunton specifying the period as once in three weeks. All but one speak highly of the use of note-books; five object strongly to examinations from without, two find them useful. Bradford, Clifton, Taunton, Wellington celebrate the good effects of science as a school subject, from its stimulating power, its bringing apparently dull boys to the front, its inculcating a comprehension of physical law. Six schools make practical laboratory work compulsory; one, Clifton, has regard to special aptitude shown by boys; one alone, Bradford, would not enforce it at all.

The evidence as to cost is complicated; the questions were well arranged, but many of the answers give aggregate sums, without saying how many boys the outlay was calculated to supply. It would seem, however, that the costly appliances of Clifton, including chemical and physical laboratories and lecture-rooms with fittings of every kind, cost about 5*l.* per head of pupils intended to be taught; those of Newcastle about 4*l.* per head; of Giggleswick 3*l.*; of Taunton less than 2*l.*: that is to say, chemistry and physics may be taught for ever to one hundred boys with an original expenditure of 200*l.*, and cannot where money is plentiful cost more than 500*l.* For the further consolation of beginners and of poorer schools we learn that a Clifton master's apparatus for three chemical and three physical lectures a week cost 8*l.* once for all, exclusive of air-pump and balance, and that in lecturing for five years he has not spent 3*l.* a year; while the Taunton master announces that a man with leisure and dexterity to make his own apparatus can begin with table, gas, water, a few shelves, and 5*l.*; and adds that his own lectures cost only 6*d.* each.

Valuable opinions are reported as to the influence exercised by the universities on school teaching. All head-masters know that the mischief inflicted on education by the Oxford and Cambridge system is incalculable, and the opinion finds expression in these answers. To gain a science scholarship a boy must abandon during the last two or three years of his school course all subjects except science, with such a minimum of classics and mathematics as may secure him against a pluck in the Little-go; and, *mutato nomine*, the same is true of candidates for either classical or mathematical scholarships.

---

[1] Appendix to Report of Head-Masters' Committee, 1877. Answers to Questions on Natural Science.

[1] This is from private information. The returns given in the Report are not so high.

VOL. XVII.—NO. 434

Those who think that school education should be general; that literature, mathematics, and science should share it in fair proportions; and that entrance scholarships at the university should be awarded to general excellence, will understand how the present system disheartens every thoughtful educator, who groans over the intellectual development of his best boys distorted in obedience to this tyranny of special prizes, which he nevertheless must win, or forfeit his reputation as a teacher.

An exhaustive list of text-books is given by the various schools. Some of them are valuable to the teacher only; others indispensable to the pupils. With very few exceptions their price is exceedingly moderate, though expensive books such as Watts' "Dictionary of Chemistry," and Weinhold's "Practical Physics," should have their place in the school library as books of reference.

It is clear that the publication of this Report marks a step in advance along the path of scientific education. It contains not opinions, but facts; not theories of what the teaching should be, but records of what it is; and this not scattered through the discursive pages of a Blue-book, but condensed into a pamphlet of thirty pages. Not less instructive is the comparative unanimity with which different schools, swayed by independent traditions, advancing on different lines, and ignorant of each other's movements, have worked out the same practical results and are teaching the same subjects by the same methods. The problem is virtually solved; the difficulties inherent in the recasting of an ancient system have disappeared so soon as they were honestly faced; and the head-masters, who perhaps looked shyly on advice from without, will listen to it, let us hope, when recommended by their colleagues. To this end the contents of the Report should be summarised, and circulated amongst the schools. It would be easy for the head-masters and science-masters of the schools which have answered questions to constitute an informal committee. A small working sub-committee would soon formulate a scheme of science teaching, based on the conclusions of the Duke of Devonshire's Commission, giving accurate particulars as to methods, books, tests, and cost of teaching chemistry and physics, with further information on the subject of museums, workshops, botanical gardens, and observatories; and this paper, drawn up in the simplest and most practical shape, might be sent at once to all first-class schools with the imprimatur of the entire committee. It would hardly fail to gain converts amongst present schools; each new head-master, appointed, as they are appointed now, with an understanding that they shall find room for science in their curriculum, would hail it as of the highest value; and when compulsory legislation comes, as come it must, the necessary details will all be ready to its hand.

W. TUCKWELL

FRANKLAND'S RESEARCHES IN CHEMISTRY[1]

Experimental Researches in Pure, Applied, and Physical Chemistry. By E. Frankland, Ph.D., D.C.L., F.R.S., &c. (London: Van Voorst.)

THE section (II.) that Dr. Frankland devotes to his researches in Applied Chemistry is not the least interesting of the work, though the chief topics are Gas and Water. The author's investigation of White's process for manufacturing hydrocarbon gas by passing steam over red-hot coke, and carbonising the gas in the retort, led to the clear distinction of the illuminating from the non-illuminating constituents of the hydrocarbon gas and of ordinary coal-gas. It was shown that marsh gas is valueless as a light producer during combustion, and that the luminosity of a gas flame is due to the heavier hydrocarbons present, whose illuminating value can be deduced from analysis and expressed in terms of olefiant gas. Such an indirect method of estimating the illuminating value of a sample of gas is certainly interesting, but it is clearly unsafe; for it involves the assumption that the illuminating value is directly proportional to the percentage of a hydrocarbon mixture of unknown constitution, calculated somewhat empirically into equivalents of the well-defined ethylene. Moreover, some recent experiments by Dittmar seem to show that ethylene does not contribute nearly so much to the luminosity of a hydrogen gas flame as benzole vapour. Hydrogen containing as much as 10 per cent. of ethylene gave a very feebly luminous flame, while hydrogen charged with only 3 per cent. of benzole vapour afforded a brilliant light when the gas was burned. Fortunately Dr. Frankland does not wholly rely upon the method in comparing -as he does in his introductory remarks on the gas investigations—the London supply of 1851 with that of 1876; for he has partially employed the photometer as a check. In 1851 the London gas supply contained 7·01 per cent. of olefiant gas, or its equivalent of other illuminating hydrocarbon, while in 1876 the percentage was 7·02. From these data it was concluded that there was no difference in illuminating power although the 1876 gas should be, according to the Act of Parliament, four candles better than that of 1851. Dr. Frankland says:—

> "The improvement of the coal gas sold in London has been only imaginary, for no real alteration has been effected. It has been made to appear better, by testing it with improved burners; but, as consumed by the burners almost universally employed, it gives no more light in 1876 than it did in 1851—a conclusion which is confirmed by the results of simultaneous comparative trials made by Mr. Humpidge with two burners, one of them similar to those by which London coal gas was tested in 1851, and the other, the so-called 'gas referee's burner,' at present employed in testing London coal gas. At 4 P.M. on June 6, 1876, the gas supplied by the Chartered Company to South Kensington Museum gave, when consumed at the rate of five cubic feet per hour from the 1851 test-burner, a light equal to 11·1 standard candles, and on June 28, at 3 P.M., a light equal to 10·5 standard candles; but when the same gas was tested at the same hours by the present referee's burner, it gave, when consumed at the same rate, a light equal to 14·3 candles on June 6, and a light equal to 14·5 candles on June 28."

There is no doubt that the photometric determinations in the above cases substantially agreed with the analytical results, which latter may, in consequence, be accepted so far. The general result, however, is eminently unsatisfactory to all persons interested, save the gas company.

The second inquiry undertaken in connection with gas was that of the igniting point of coal-gas. The chief facts elicited possess so much general interest that we may mention them here. They were:—1. That coal-gas ignites at a much lower temperature than marsh-gas, but at a higher temperature than hydrogen or carbonic oxide.

---

[1] Continued from p. 219.

2. That the admixture of the vapour of carbon bisulphide does not sensibly lower the igniting point of coal-gas, although alone, or mixed with hydrogen or carbonic oxide, this vapour inflames at 400° F. 3. The Davy lamp, which is a protection in explosive mixtures of air and firedamp, is not safe in similar mixtures of air and coal-gas.

The third paper in the section discusses the possibility of making metallic magnesium available as a source of artificial light: and the last paper, relating to the use of illuminating materials, describes the construction of a gas-burner, in which the waste heat of the flame is made to raise the temperature of both air and gas to 500 or 600° F. before combustion, and thus to increase the luminosity of the flame.

The author's group of papers on water examination and purification, and on the treatment of sewage and other refuse, occupies nearly 300 pages of the volume before us. The value of Dr. Frankland's investigations in sanitary chemistry has been variously estimated, and a glance over the pages before us recalls the wordy warfare that has been waged between the upholders of Dr. Frankland's system of water analysis and of the conclusions founded upon the data afforded by it, and those that put their trust in the method devised by Messrs. Wanklyn, Chapman, and Smith. We anticipate that the republication of Dr. Frankland's papers will impart fresh vitality to a controversy that seemed, happily, to be on the wane. If, however, a renewal of the controversy is likely to lead to re-investigation and substantial improvement in the existing methods of water analysis, we shall not regret the re-opening of the subject.

The chief aim of all modern methods of water analysis is the detection and estimation of organic (especially sewage) contamination. Dr. Frankland seeks to attain the end in view by direct estimation of the "organic" carbon and nitrogen in the water, while Messrs. Wanklyn, Chapman, and Smith attempt to estimate the nitrogenous organic matter in water by breaking up the organic bodies and separating their nitrogen in the form of ammonia—"albumenoid ammonia." A rather extended experience in the use of both methods has led us to conclude that Dr. Frankland's plan, though nearly perfect in point of theory, is not as satisfactory in practice; while the rival method rests on a bad foundation, but is not likely to lead to error in excess. We may state this much without trenching too far upon technical ground, but we do so in order to justify the desire above expressed for a re-investigation of the subject, conducted with a view to render the theory and practice of water analysis equally satisfactory.

It is scarcely necessary to mention that we find in this section Dr. Frankland's valuable papers on the development of fungi in potable water; on the deterioration of potable water during its passage through cast iron mains and leaden service pipes; on the methods of softening "hard" water, and on the comparative purity of water from various geological strata, and from different sources such as mountain streams and lakes, rivers, shallow wells, artesian wells, and springs. In addition, experimental data are given showing the extent to which polluted water can be purified by various means and rendered fit for domestic purposes. These papers, together with those on sewage treatment, are of especial value to sanitary engineers, and will no doubt be more freely consulted in their present well-connected form than when scattered through other publications.

In Section III. Dr. Frankland returns to gases and vapours—evidently favourite subjects of study with him since the date of his discovery of the alcohol radicles—but now from the physical side. The first investigations detailed in the section are those upon the effect of pressure on combustion, which led him to conclude that the luminosity of ordinary flames] is chiefly due to the presence of incandescent vapours or gases of high density, rather than to solid particles. The author's experiments on the combustion of hydrogen and carbonic oxide under great pressure proved that incandescent gases and vapours emit light in proportion to their density, and that a continuous spectrum can be afforded by dense gas as well as by solid or liquid matter. These observations led to the suspicion that the sun's photosphere consists of gases or vapours only, and ultimately to the commencement of a new line of research in conjunction with Mr. J. Norman Lockyer, who was then engaged on his researches on the physical constitution of the sun. Dr. Frankland was soon obliged to relinquish the investigation, owing to pressure of other work; but in Mr. Lockyer's hands it has since afforded results of the highest interest and value.

Excluding a chapter on climate, and some miscellaneous observations, the last research detailed in the volume before us is a highly important one on the source of muscular power. This inquiry is really complementary to the well-known investigation of Profs. Fick and Wislicenus on the same subject, for Dr. Frankland ascertained by direct calorimetrical determinations the potential energy locked up in muscle and in its chief products of oxidation urea, uric acid, and hippuric acid and proved that the store available was much less than would suffice to account for the work done by Fick and Wislicenus in the ascent of the Faulhorn. Frankland's experiments conclusively proved that the muscular force expended by the two professors in the ascent of the mountain must have been chiefly derived from the oxidation of non-nitrogenous matters, since it could not have been produced by the oxidation of muscle or other nitrogenous constituents of their bodies. This investigation is one of the most valuable in the section, and will be re-read with special interest in connection with the Rev. Prof. Haughton's latest researches.

We cannot conclude this short sketch of Dr. Frankland's admirable researches without giving expression to the hope we entertain that the well-arranged volume before us may prove to be but an instalment of the life-work of its distinguished author.

J. EMERSON REYNOLDS

FLORA OF TROPICAL AFRICA

Flora of Tropical Africa. By Daniel Oliver, F.R.S., F.L.S., Keeper of the Herbarium and Library in the Royal Gardens, Kew, and Professor of Botany in University College, London. Assisted by other botanists. Vol. iii. Umbelliferæ to Ebenaceæ. Published under the Authority of the First Commissioner of Her Majesty's Works. (London: L. Reeve and Co., 1877.)

THE third volume of Oliver's "Flora of Tropical Africa" includes fourteen natural orders, mostly belonging to the sub-class Gamopetalæ of the Dicotyledons. The two orders, Umbelliferæ and Araliaceæ, both by Mr. W. P. Hiern, and occupying the first thirty-two pages, were printed in 1871 along with vol. ii., the rest being all new. The district included in the present volume is of course the same as that mentioned in the previous ones, extending on each side of the equator for somewhere about fifteen degrees. It is divided into six regions, two on the west side of the continent, distinguished as Upper and Lower Guinea, two on the east side; Nile Land and Mozambique and the intervening region divided into the north and south-central. The district is therefore one of vast extent, and will probably yield many new forms when further exploration renders our knowledge of the country and of its productions more complete than it is at present.

The Umbelliferæ are represented in the flora by twenty-one genera and about forty-four species. The number of genera is small when contrasted with the thirty-four found in Britain. Several familiar British forms are found in this flora, of which it will only be necessary to mention *Sanicula europæa*, *Conium maculatum*, *Anthriscus sylvestris*, *Daucus carota*, and *Caucalis infesta*. Five genera are, however, endemic in Africa. The genus *Peucedanum* is interesting as including two species, *P. araliaceum* and *P. fraxinifolium*, both small glabrous trees. The Araliaceæ are unimportant, and represented by only three genera and fourteen species.

By far the most important monograph in the present volume is that on the Rubiaceæ, by Mr. W. P. Hiern. It occupies over 200 pages, or nearly as many as the monograph of the Compositæ, the joint production of Messrs Oliver and Hiern. The Rubiaceæ form a very extensive tropical and sub-tropical order, most richly represented in America. Tropical Africa, however, possesses seventy-eight genera, about thirty of which are endemic, and three of these are now described for the first time by Mr. Hiern. The genus *Coffea* is fully treated of by Mr. Hiern. The *C. arabica* occurs in four of the districts of the flora, but not in the two Central regions. The new coffee, *C. liberica*, Hiern, which promises to be of so much value, is here noticed. It is the source of the Liberian coffee, and probably of the Cape Coast coffee. The berries are said to be larger, the flavour finer, and at the same time the plant is more robust and productive than the ordinary *C. arabica*. The *C. arabica* has the flowers pentamerous, while in *C. liberica* they are 7- or 6-merous; or, according to the key to the species, 6 to 8-merous. The genus *Sarcocephalus* is an interesting one, the fruits cohering to form a pseudocarp known as the peach, or country fig, of Sierra Leone. The shape and colour of the pseudocarp is that of a strawberry, but in flavour it resembles an apple. Unfortunately if eaten to excess it acts as an emetic. Two familiar species of *Galium* are also included in the flora, namely, *G. aparine* and *G. mollugo*.

The Valerianaceæ are represented by the European *Valerianella dentata* only. The Dipsaceæ by three genera, *Scabiosa* yielding two familiar species. Both these small orders are by Mr. Hiern.

The Natural Family Compositæ, the joint production of Prof. Oliver and Mr. Hiern, occupies the chief place in the volume, as would be expected of the largest order of flowering plants. The number in the tropical region of Africa, 468 species, is small compared with the 1,300 species occurring in the Cape flora. In tropical Africa there are 117 genera, seventeen being endemic, and all of these latter either small or monotypic. Many of the forms are of great interest, and some of the genera very extensive. It is curious to meet with *Erigeron alpinus* in Abyssinia, along with *Senecio vulgaris*, and others, some of them familiar weeds. The genus *Tarchonanthus* forms a small tree, and it was upon a species of this genus that Dr. Welwitsch found the only species of *Viscum* he met with in Angola.

The Campanulaceæ are by Mr. W. B. Hemsley, who reduces the peculiar Abyssinian plants known as *Tupa* to the genus *Lobelia*, and describes two species, *L. rhynchopetalum* and *L. giberroa*. One species of *Lightfootia*, from Lower Guinea, is of interest. In it (*L. welwitschii*) the ovary is almost wholly superior, while in all others the ovary is inferior, the plant thus looking very unlike the other members of the Campanulaceæ. Four genera of Ericaceæ occur, but only one species of *Erica*, viz., *E. arborea*, thus contrasting with the Cape flora where the species are most numerous. The Ericaceæ, Plumbagineæ, and Primulaceæ are by Prof. Oliver, but are small and unimportant. The Myrsineæ and Sapotaceæ are by Mr. J. G. Baker, and the Ebenaceæ by Mr. Hiern, who has already published a monograph of this group.

The greater part of the volume is by Mr. Hiern, who contributes about 270 pages, while, along with Prof. Oliver, he contributes 207 pages more. About twenty pages each are contributed by Messrs. Baker and Hemsley, while eight only are from the pen of Prof. Oliver alone. This handsome volume of about 550 pages adds another to the long series of "Floras" now so well known and so highly appreciated that have from time to time issued from Kew.

W. R. McNab

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Marine Fossils in the Gannister Beds of Northumberland

I TAKE the earliest opportunity to announce, through your columns (if you will allow me to do so), that on the 9th of this month (February), while conducting the usual weekly field-work in connection with this college, I had the good fortune to find marine fossils in the lower coal measures, or gannister beds of Northumberland. The locality is about half-way between the Stocksfield Station, on the Newcastle and Carlisle Railway, and the village of Whittonstall. As I have more than once insisted on the fact that hitherto no marine forms had been found in this series in this country, I wish to be the first to destroy the effect which that negative evidence may have produced. The importance which the study of the gannister fauna has assumed since the publication of Prof. Hull's recent paper on the Classification of the Carboniferous Rocks in the *Quarterly Journal of the Geological Society*, need not be dwelt on.

Full details of the find will be published elsewhere.

G. A. Lebour

College of Physical Science, Newcastle-on-Tyne, February 12

Liquids having a Specific Heat Higher than Water

In Nature, vol. xvii. p. 252, it is stated: "Hitherto water has been regarded as possessing a greater specific heat than any other body excepting hydrogen. E. Lecker has shown to the Vienna Academy that mixtures of methylic alcohol and water have a specific heat higher than that of water, and accordingly take the second place," &c. Can you spare me a corner to point out that in 1869 the specific heats of some mixtures of ethylic alcohol and water were proved by Dr. A. Dupré and myself to be considerably higher than that of water, *e.g.* a mixture containing 20 per cent. alcohol, has a specific heat of 104.3, water = 100 (*Phil. Trans.*, 1869, 591; Watts's Dict., 2nd Supplement, 475). Moreover, we especially mentioned "that our experiments furnished the first example of a liquid having a specific heat higher than that of water." Since 1869 Dr. Dupré has estimated (*Proc. Roy. Soc.*, xx. 336) the specific heats of mixtures of methylic alcohol and water without finding any such mixture to possess a specific heat above that of water.

Age of the Sun in Relation to Evolution

I HAVE read Mr. Plummer's letter along with his article in the *Popular Science Review*, and am surprised at his objections to my paper on the "Age of the Sun's Heat."

It matters not whether the sun's heat was derived from the contraction of his mass or from the falling in of meteorites, or of comets, as advocated by Mr. Plummer in the article referred to, we could only have had a supply of heat sufficient for twenty or thirty million years, at the present rate of radiation. Probably not much more than half of this would be available for the formation of the stratified rocks, and the development of life on the globe; a length of time irreconcilable alike with geology and evolution. We are therefore compelled to look for some other source than gravity as the origin of the sun's heat. It will not do to lengthen this period by assuming that the rate of radiation was less during past ages than at present, because we should have to assume that the temperature in the past was also less, a conclusion at variance with the known facts of geology and of paleontology. I never supposed that the rate of radiation in the past may not have been greater than now. Nor did I ever suppose that there is any antecedent improbability whatever in the collision of stellar masses. What I maintained (*Quart. Journ. of Science* for July, 1877) was that the formation of a sun is an event which, on an average, can only be witnessed once in about 15,000 years, or the number of visible stars would be greater than it actually is. And this, I think, is a sufficient reason why we should not expect any historical record of such an event. Further, it does not necessarily follow that the two bodies coming into collision should possess equal mass or velocity in order to have their motion of translation converted into heat. If it be true that the stars derived their heat from loss of motion then this may quite well explain why their motions are so small. In a word, the energy which the sun has been dissipating into space through past ages, always existed in the form of motion. Collision only changed it from one form to another, viz., from the motion of translation to molecular motion.

JAMES CROLL

The "Phantom" Force[1]

IT might be supposed that permanent and entirely local or "internal" force-pairs of this kind acting on innumerable material couplets in a system would so disturb the individual energies of their motions that no general conclusion as to the total change of energy during the progress of such a system's motion could be drawn; but the simple law that impulses act independently of each other and of existing motions soon shews that the whole gain of energy in the system is the sum of the separate gains in the several mass-couplets due to their absolute or several actions and reactions at every instant of the motion, and that when these abstract force-pairs are all permanent, the above constancy of the sum of their actual and potential energies is possessed by the whole system as perfectly as would be the case by one only of its couplets, or component pairs. That this is not merely an abridged expression for the resulting actual energy in all the possible different phases that such a system may go through, briefly stated for any initial and final configurations and initial motion of the system by means of the negative scale or potential function of all the several component force-pairs supposed known; not merely, that is to say, a logical consequence of arbitrary and fanciful definitions, but a conclusion full of importance and of real natural signification depends, firstly, upon the fact that the thing defined as "impulse," or the gradient of the scale, which is here independent of the time and depends only on the mutual configuration, is not permanent by a very rare occurrence, but that it is often so, and under very various circumstances; and again that this impulse, or flux of momentum, or gradient of energy, occurs in many other motions with conditions of equal simplicity; and lastly, and above all, on the fact pointed out at the beginning of these reflections, that while we are able to use, and of our free will to call into existence force in innumerable ways, we learn from our experience that this impulse is invariably *caused or dictated by* a certain special efficacy or compulsion, which our power of exercising it as we please so as either to annul, to modify, or to increase it at will with the consequence of obtaining with it any effective impulses that we desire, shows us to be a different kind of quantity from the impulses that we either thus obtain, or that we see it producing in surrounding nature. Newton's second law of motion in fact recognises this specific difference between the magnitudes of a force and of its effect, when it asserts that forces *produce their whole effects* (that is to say, remain unaffected in their efficacies) whatever may be the state *of rest* or of motion of the bodies upon which they act. As it is found that forces or compulsions (measured as they are in statics by additions, subtractions, and oppositions to a standard force) are always proportional to the free impulse, or undisturbed acceleration of a mass-unit which they can produce, so that by taking the impulsive effect and the active compulsion of any one standard force as the units for measuring these quantities respectively, they are then said to be numerically equal to each other in every force; it yet follows from their specific independence that they are not identical in kind as they are in measure. The same is true of the products obtained by multiplying them separately by any small space through which a force acts; and it would be an obvious misstatement to assert that the sum of the works of a compulsion, and of the free impulse which it produces taken negatively, is constant when a force acts freely; because this would be confusing in one sum two different quantities; a result which it seems must arise from the simple fact that our part in mechanical "compulsions" distinguishes and removes them from the category of impulses to which they would otherwise belong, and leads us to regard them as *the causes of* the impulses which we observe. The language adopted by Newton (and used also by D'Alembert) in the proposition quoted at the beginning of this letter is that in a proper mechanical system, *compulsions equal to* the observed impulses reversed, will (as is obvious) arrest in their origin all changes of motion in the system, and will (with the immutable force conditions proper to the system) hold in balance, or give a complete account of all the forces (other than those immutable ones) acting upon it. Using the principle of virtual velocities in this case of equilibrium of balancing forces, Newton expresses the rule for exploring all the mechanical efficacies (superadded to the immutable ones) acting in the system by concluding that the sum of all the similar "works of *compulsion*," or of all the "actions" in a short time corresponding to a small motion of the system, when the reversed ones have been introduced, will be a constant quantity. Thus both Newton and D'Alembert agree in this, that they recognise in forces *causes which differ from* the effects which they produce. By what similar laws of work found to hold true in a proper conservative system the modern science of energy (which deals with the phenomena of causation in a wider and more diversified form) seeks to extend the method of cancelling the counteracting causes, or the principle of energy conservation here laid down by Newton for a mechanical one, to the far larger, but less thoroughly explored and exhausted field of all the onward flowing streams of physical agencies which we perceive following their natural bents or inclinations around us, I will presently endeavour to explain. It should be noticed in connection with this general extension of the principle, that the "work" of a force *in a short time*, however fixed its efficacy, or its rate of doing work *in a short space* (or of producing *momentum* in the short time) may be, is incidental, and not a fixed quality of the agent force like its faculty of tension, since a force as often diminishes as increases actual energy by a momentary action, and thus no fixed rule is drawn from the natural tendency of force to impart momentum, that potential energy necessarily becomes, or even necessarily tends to become, actual energy in every mechanical energy-transformation. The mechanical stress of friction is an example of the opposite tendency; and it also furnishes us with an example of a force whose *working power* only, and not its motive tendency, is a mechanical "*agent*" which we can summon up at will; but of which we still regard the motive tendency as similar to that of other mechanical forces, because it can maintain equilibrium with them.

---

[1] Continued from p. 303.

If the natural office of force as a bond between space and matter is to ward off contact between material points, and to endow them with impenetrability (for this marked feature as far as it has been explored appears to be inherent in all matter) by absorbing at the proper places the energy of motion, and by curbing and accelerating it elsewhere according to these dictates, it must be implanted in material points in such permanent pairs as have just now been described; for the third law in Newton's master-summary is often held (with how much correctness, perhaps, may be questioned), to assert that all the forces of nature consist of an action and a reaction in equal and opposite pairs, and be omnipresent with a particle to protect it, its permanent impulse, or rate of doing work, being at the same time referrible to the space or distance between the mutually impinging, or colliding pair of atoms. A mechanical system so constituted, as we have seen, if not disturbed by the forces of foreign bodies outside of it will have the sum of its actual and potential energies constant. If we include those foreign bodies (endowing their forces at the same time with persistency), and if we find that the whole material universe as far as we can explore it admits of being comprehended in one system of this kind, a mechanical explanation of all known physical agencies might thus, apparently, be arrived at. In every particular of the motion of any group of bodies in it, however, except the single one of its total energy, we would be obliged to abandon (as Newton does) the local centres of reckoning of the several force pairs, and betake ourselves to the mass-centre of the group as our origin of reference for noting all the forces, and tracing all the motions of a body completely in its wanderings through the system. If this obligation, and the end to which it leads us of referring force at last to perfectly abstract realms of space and matter terrifies and affronts the scientific sense, it is sufficient consolation to observe that if force were not ultimately so referred, and if its impulse was exerted in those local spaces only in which we find it acting apparently as a simple action and reaction, there would be as many distinct kinds of energy of motion and of configuration (which we would still retain as expressing the local laws of force) as there are local spaces, with countless complex rules for mutual equivalence of these several energies connected with the common path of the body in several of them together, which would effectually defy even a modern physicist to disentangle and employ! We may rest thankfully contented with the laws that Newton has traced out. But does the simple mechanical system which we have just imagined really represent that of nature? Are nature's force pairs really all permanent? (We will suppose that they are all dual and reciprocal, for, as will presently be noticed, a special and peculiar explanation only can be given of forces which are absolutely external or solitary without any physical qualification); and is the sum of their mechanical energies a constant quantity, as we know that it becomes when all the other kinds of energy in material nature are added to it? The answer is very obvious, but it betrays at the same time a complete ignorance of the extent and depth of the question that we put. The readily-preferred response is "No; the sum of the mechanical energies, as far as they can be recounted, is not constant, for numberless forces, and mechanical energies proceeding from them are being constantly produced by heat, radiation, chemical action, and other physical agencies, or are being employed to renovate those agents with energy in equivalent stores, but whose special kinds *are not* mechanical." At the same time the progress of physical inquiry reveals to us in the operations of these agents microscopical, or rather hyper-microscopical, actions of force, and invisible charges of actual energy, with which our earlier knowledge of these agencies was entirely unacquainted, and a little step of inductive generalisation only is needed (I believe that this view was unfolded by Helmholtz many years ago, but I have not been able to rediscover his remarks and demonstrations[1]) to suppose that all physically-generated forces form but visible and changing resultant-links in an invisible chain of persistent forces, of which we hold some of the most prominent loops in our hands, and thoughtfully wonder what they are.

In his Glasgow lecture on "Force" (in NATURE, vol. xiv. p. 463), an important hint was offered by Prof. Tait regarding an apparent character of potential energy, founded on the mathematical condition that quantities whose units of measurement are of the same dimensions in space, mass, and time, are of the same kind. It follows from this that the potential energy of a force, or the energy received from and transferred to it is of the same kind as actual energy of material motion, because they are both measured by the same combination of the units of space, time, and mass.

Let us first observe that it cannot be *matter* in motion which constitutes the potential energy, unless this matter can traverse itself and other matter freely (because, itself the cause of force, it cannot itself experience any), and therefore that it is something not matter, but both resident in and proportional to matter, and also free; and that its energy of motion as an occupant of matter is actual, and in a state of freedom is potential energy. Imagine a perfect reflection of the material universe to be formed by a plane in space; then the changes of energy of motion of the reflected image of any mass particle taken negatively are equal and opposite to the similar changes of energy of the particle itself, and would measure in a kinetic form the amount of the work of force upon it; but the *tendency* of energy of this form and of the actual form to pass into each other would not be accounted for. In our present knowledge of its transformations it scarcely seems possible that a simpler picture of potential energy as a form of energy of motion than this downright imitation of the actually-existing motions could be reasonably offered. The proposition that force must be a process of transformation of *a new energy of motion*, so astonishingly complex, I confess staggered me, and even led me to doubt if the simple laws of force and motion laid down in the "Principia" could be really so perfect and complete as they appear, amid the pell-mell of motions which the thought suggests! I began this letter shortly before going to Plymouth, intending to recommend much *more* careful experiments than even Mr. Crookes has carried out with the radiometer, and with his recent, most effective form of the instrument, the otheoscope, in order to test and examine the question of the laws of force (especially with the idea of possibly isolating a single force) seriously; and though much induced to do so by the warm and timely words of commendation passed on Mr. Crookes' labours in his opening address to Section A at Plymouth (NATURE, vol. xvi. p. 314) by Prof. G. C. Foster, I have been unable from other occupations to finish it until now. But I have entirely abandoned my original intention, in great part, by reason of a new light on the exceedingly abstruse and puzzling question which the able remarks by "X" in NATURE (vol. xvi. pp. 438, 457) have afforded me about the real characters of force and of potential energy.

Newcastle-on-Tyne A. S. HERSCHEL

(*To be continued.*)

Cumulative Temperatures

UNDER the above heading, among the "Meteorological Notes" in your issue of last week, I notice the announcement that "To simplify the difficulty of obtaining sums of temperature . . . M. von Sterneck has recently proposed to obtain these indirectly by observation of the sums of actions produced by the temperature." And that M. von Sterneck's proposal is to employ for this purpose a pendulum clock in which the variation of rate due to the raising or lowering of the centre of gravity of the pendulum under variations of temperature is, through its influence upon the daily error of time shown on the dial, employed for determining the mean temperature of the air throughout the twenty-four hours. And the notice concludes by saying that M. von Sterneck has also proposed to apply the same principle to determine the variations in atmospheric pressure and in the intensity of magnetism.

In reference to this subject it is only right to point out to the readers of NATURE (a term synonymous with the general body of lovers of science all over the world) that the merit of these suggestions is, by priority, due to one of our own countrymen, Mr. W. F. Stanley, who, at the *soirée* given by the President of the Royal Society as far back as April, 1876, exhibited two instruments in which the chronometrical method of determining thermometric and barometric averages was carried out with very marked success.

One of these to which the name chrono-thermometer was applied, consisted of a clock, the pendulum of which was a mercurial thermometer, its centre of gravity being raised or lowered by the expansion or contraction of a column of mercury under variations of temperature. In the other instrument, or chrono-barometer, the pendulum consisted of a glass tube containing a column of mercury, the rising and falling of which under influences of barometric pressure raised or lowered the centre of gravity of the pendulum and varied the rate of the clock accordingly. The clock-train in both instruments was so arranged that the dial-readings could, by an exceedingly simple calculation, be interpreted in terms of mean daily thermometrical or barometrical variations. As the alteration in the lengths of the pendulums takes place second by second throughout the day, it follows that the daily error of time shown on the dial must be proportional to the mean of the variations of the thermometer or barometer during the same period.

---

[1] They are, I find, contained in a paper of some length in vol. vi. of "Taylor's Scientific Memoirs," 1853, pp. 114—162.

The method of estimating, by observation of the rate of an uncompensated time-keeper, the mean amount of heat received during any given period, without the necessity of recording the actual temperature at any particular time, is not by any means new, for the chronometrical thermometer, an instrument which has for many years been employed at the Royal Observatory for testing the rates of chronometers under variations of temperature, is founded upon the same principle. This instrument consists of a chronometer in which the usual compensation for temperature is reversed; that is to say, in the balance the positions of the brass and the steel are interchanged, the latter being outside, so that variations of temperature produce an exaggerated effect upon the rate of the instrument.

M. von Sterneck is probably the first to suggest the employment of the chronometrical method to the determination of mean variations in the vertical intensity of terrestrial magnetism, but he has, I think, been anticipated in its application to the computing of thermometric and barometric averages.

Scientific Club, February 18 CONRAD W. COOKE

BACTERIA IN WATER

IT is well known that water—whether tap or ordinary distilled—possesses the property of contaminating, with a growth of bacteria, any "cultivation" liquid inoculated with it, but the morphological condition in which these organisms occur in it is open to question; it may be supposed on the one hand, that they exist as developed bacteria, and are not apparent under the microscope merely in consequence of their scarcity, as shown by Mr. Lister in the account of his recent admirable investigation of the lactic fermentation, to be the case with some specific ferments, or, on the other hand, that they are present as "germs" of the bacteria, bodies yet far more minute than the mature forms, and on that account invisible—ultra-microscopic. Which of these alternatives is true I have endeavoured to determine by experiment, the details of which will shortly be published, and the general result is here briefly communicated.

M. Pasteur has recently stated in the *Comptes Rendus*, that if a cylinder of water be allowed to stand for several weeks at a constant temperature, the organisms in it sink to the bottom, leaving the upper portion free, and incapable of contaminating. Following this method and placing a vessel of ordinary distilled water in an apparatus constructed for the purpose of maintaining an invariable temperature, after seven or eight days a specimen of the water was taken from the bottom of the vessel by a pipette closed with the finger and dipped into it. The water so taken was in appearance perfectly bright and pellucid, but under the microscope it was found to contain amorphous particles, some spores of filamentous fungi, micrococci in great numbers, bacteria of the common form (*B. Termo*) and bacilli (long and extremely slender filaments). All of these forms were motionless, or exhibited only Brownian movement. No such forms could be detected in the upper layers of the water, nor in a specimen taken from the bulk of that from which the experiments were made. As regards limpidity, there was no difference between the top and bottom portions.

I have made four experiments with specimens of water obtained from two different sources, and in all I have been able by this method of subsidence to prove the presence of organisms in great numbers in the sediment. It may be mentioned that they stain with facility by Hæmatoxylon, and are thereby rendered more readily apparent.

These observations show that bacteria occur in water under their usual forms, and that they are not generally distinguished on account of their small number, in any one portion of the water, when disseminated through its mass. The observed contaminating property of distilled water is thus accounted for without necessitating the assumption of "germs" of any sort, an hypothesis which is unsupported by observation.

The examination, by cultivation, of the difference in contaminating properties of the upper and lower layers, stated by M. Pasteur to exist, has as yet been inconclusive.

G. F. DOWDESWELL

OUR ASTRONOMICAL COLUMN

THE URANIAN SATELLITES, ARIEL AND UMBRIEL.—The following positions of the two interior satellites of Uranus for the ensuing fortnight are derived from the data furnished by Mr. Marth in the January number of the *Monthly Notices* of the Royal Astronomical Society, and are for 11h. G.M.T., or about the time of the planet's meridian transit. There must be many telescopes in this country which will command the two exterior satellites, Titania and Oberon, but, so far as we know, neither Ariel nor Umbriel have yet been certainly observed here with any but Mr. Lassell's reflectors. Prof. Newcomb states that Ariel is intrinsically brighter than Umbriel; he thinks that Ariel at least belongs to that class of satellites of which the brilliancy is variable, and dependent on its position in its orbit, and he adds that the evidence of variability of some kind seems indisputable, since he has repeatedly failed to see it with the Washington refractor when the circumstances—distance from the primary not excepted—were favourable, and when the next satellite, Umbriel, though less favourably situated, was visible. "On the other hand," he remarks, "there were two occasions, 1874, January 28, and 1875, March 25, when it was surprisingly conspicuous," and at these times the angle of position was about 350°. Prof. Newcomb further expresses the opinion that where any difficulty is experienced in seeing the outer satellites, he would not hesitate to pronounce it impossible to see the inner ones.

Nevertheless, the success which has attended the search for one, at least, of the satellites of Mars by English observers who are provided with large instruments, may perhaps induce them to look for the close satellites of Uranus at the present opposition.

PIGOTT'S OBSERVATIONS OF VARIABLE STARS.—Some years since it was suggested, we believe, by Prof. Argelander, that the Royal Society might have in its possession manuscripts of Edward Pigott of York, amongst which might be found observations of variable stars that would prove of importance in the history of their fluctuations. It would appear, however, that none of Pigott's papers are preserved in the Society's *Archives*, an ineffectual search having been lately made for them.

THE TEMPLE OBSERVATORY, RUGBY.—Mr. G. M. Seabroke, as Curator of the Temple Observatory, has issued a Report upon proceedings during the year 1877. The whole of the measures of double-stars, 398 in number, during the last three years up to the time of dismantling the old Observatory, have appeared in vol. xliii. of the *Memoirs* of the Royal Astronomical Society. More recently investigations into the motions of stars in the line of sight by the spectroscopic method have occupied Mr. Seabroke's attention, but the chief work in the year has been the rebuilding of the Observatory. The Report contains an outline of its history and a description of the instruments to which reference may be made in future years. The equatorial of 8¼ inches aperture, by Alvan Clarke, was formerly in the possession of the Rev. W. R. Dawes, and an interesting letter from him upon its capabilities is appended to the Report. Not the least notable of its performances is its having shown the close satellite of Saturn, Mimas, on many occasions, and we know that its former possessor was not likely to have mistaken faint stars for the satellite.

The observatory is open to the members of the school at certain hours on fine evenings when opportunities for observing with the equatorial and transit are afforded them. It should be mentioned that in addition to the Alvan Clark refractor the observatory possesses a twelve-inch With reflector which is chiefly used with the spectroscope.

The cost of the new observatory and house for the curator, upwards of 1,230*l.*, has been defrayed by subscriptions from the masters, old Rugbeians, and others in the school, upon the occasion of its tercentenary.

GEOGRAPHICAL NOTES

AFRICAN EXPLORATION.—The two African Societies of Berlin, which are now combined, have resolved to turn their attention to practical (*i.e.*, commercial) objects as well as scientific ones with regard to the great continent in which the travels of Cameron and Stanley have revealed vast stores of the most varied products. The twin societies therefore invite all German merchants, manufacturers, &c., to participate in their efforts to open up a great African commerce, and announce that the German Government is ready to grant a preliminary sum of 100,000 marks (5,000*l.*) to further the object in question. The Germans seem determined that no single nation, more especially England or Portugal, shall have the supremacy on the Congo. In Switzerland a new geographical society has been formed for the same object as the above.—An official telegram from Zanzibar to Brussels announces the death at Zanzibar of Dr. Maes and Capt. Crespel, who were sent out by the International African Association as leaders of an exploring colony in Central Africa. With them were M. Cambier and Ernest Marno, and they were to establish a station somewhere in the Tanganyika region, which would form a centre of further exploration. The death is also announced of Capt. Elton, who, with Mr. Cotterill, was surveying the route between the north end of Lake Nyassa and the east coast.

ARCTIC EXPLORATION.—The Committee on Naval Affairs of the U.S. Congress have adopted a report from Mr. Benjamin A. Willis recommending the equipment of an Arctic expedition as proposed by Capt. Howgate. At a public meeting held by the New York Geographical Society to discuss the subject of polar exploration a paper by Capt. Howgate was read on his intended colony. Lord Dufferin, governor-general of Canada, was elected an honorary member of the Society, and returned thanks in his usual style. He referred to himself as "a potentate whose sceptre touches the pole, and who reigns over a larger area of snow than any monarch of the earth."

THE PAMIR.—We learn from the *Turkestanskiya Vêdomosti*, that two members of the Pamir expedition, MM. Skassi and Schwarz, have returned to Tashkend, M. Severtsoff remaining for some time at Osh. The expedition, which started in September last, has met with great difficulties from deep snow and the cold weather, the thermometer falling as low as 31° Celsius below zero. Owing to the absolute want of forests, wood was brought by yaks. No inhabitants were found in the Pamir, nor even in the valley of Alay, the Kirghiz having already left the valley for warmer regions. The rarity of air on those great heights, which exceed 15,000 feet, occasioned much suffering to the members of the expedition. The Valley of Alay was reached from that of Fergana, by way of the Shart Pass, and from the Alay the expedition followed the path which was followed by Gen. Skobeleff in 1876. M. Severtsoff reached as far as the Lok-sai River, which the natives said flows into the Lob-nor, under the name of the Tarim-gel. Thence he was compelled by the deep snow to return, without reaching the problematic meridional ridge which was the aim of the expedition. Prof. Schwarz has determined the latitudes and longitudes of six places, and has made numerous magnetical observations; a complete survey of the route was made by the topographers, the heights of a hundred points were determined, partly barometrically and partly geodetically. M. Severtsoff has brought in a large ornithological collection.

EDUCATIONAL TRAVEL.—We learn that a society is in course of formation at St. Petersburg for the organisation of travels for children and for young men. The travels of the children are intended for the general development of the intellectual faculties and of the power of observation, and those of the young men will be arranged so as to give them a practical knowledge of some branch of science, together with an acquaintance with their own country. The travellers will be divided into several groups natural sciences, history, ethnography, &c., and each section will be placed under the leadership of some well-known specialist. The success of the botanical and geological excursions, which were organised during several summers by the members of St. Petersburg and Moscow Societies of Natural Sciences, lead us to expect that the new enterprise will be successful.

PRSHEVALSKY AND MACLAY.—The Russian Geographical Society has received telegrams from Col. Prshevalsky, dated Fort Alexandrovsky, announcing that the traveller is now recovering from an illness, and will continue his journey to Tibet; and from Dr. Mikluho-Maclay, announcing his return from New Guinea to Singapore.

SEA TRADE WITH SIBERIA.—We learn that several Bremen and Moscow merchants have formed a company for sea trade with Siberia. A large steamer, with two barges and a small river steamer on board, will start from Bremen in July next for the mouth of the Ob or of the Yenisei. Leaving the river steamer and the barges for river communication, the large steamer will return with Siberian wares.

GEOGRAPHICAL BIBLIOGRAPHY.—In the last part for 1877 of the *Zeitschrift* of the Berlin Geographical Society will be found a copious list, covering 100 pages, of the principal geographical works published between November, 1876, and November, 1877.

RUSSIAN GEOGRAPHICAL SOCIETY.—The Great Constantine gold medal of the Russian Royal Geographical Society was awarded this year to M. Zakharoff for his remarkable Manchurian dictionary, the result of many years' study of the language and life of the Manchurians, during his residence as Consul at Kuldja. The gold medal of Count Lütke was awarded to Capt. Rykacheff, of the Physical Observatory of St. Petersburg, for his researches into the distribution of atmospherical pressure throughout Russia. Small gold medals were awarded to M. Marx for ten years' meteorological observations at Yeniseisk, and to Col. Tillo for his levelling between the Aral and Caspian.

A NEW UNDERGROUND MONSTER

A RECENT communication from Fritz Müller, of Itajahy, in Southern Brazil, to the *Zoologische Garten* contains a wonderful account of the supposed existence of a gigantic earthworm in the highlands of the southern provinces of Brazil, where it is known as the "Minhocao." The stories told of this supposed animal, says Fritz Müller, sound for the most part so incredible, that one is tempted to consider them as fabulous. Who could repress a smile at hearing men speak of a worm some fifty yards in length, and five in breadth, covered with bones as with a coat of armour, uprooting mighty pine trees as if they were blades of grass, diverting the courses of streams into fresh channels, and turning dry land into a bottomless morass? And yet after carefully considering the different accounts given of the "Minhocao," one can hardly refuse to believe that some such animal does really exist, although not quite so large as the country folk would have us to believe.

About eight years ago a "Minhocao" appeared in the neighbourhood of Lages. Francisco de Amaral Varella, when about ten kilometres distant from that town, saw lying on the bank of the Rio das Caveiras a strange animal of gigantic size, nearly one metre in thickness, not very long, and with a snout like a pig, but whether it had legs or not he could not tell. He did not dare to seize it alone, and whilst calling his neighbours to his assistance, it vanished, not without leaving palpable marks behind it in the shape of a trench as it disappeared under the earth. A week later a similar trench, perhaps constructed by the same animal, was seen on the opposite side of Lages, about six kilometres distant from the former, and the traces were followed, which led ultimately under the roots of a large pine tree, and were lost in the marshy land. Herr F. Kelling, from whom this information was obtained, was at that time living as a merchant in Lages, and saw himself the trenches made by the "Minhocao." Herr E. Odebrecht, while surveying a line of road from Itajahy into the highlands of the province of Santa Caterina, several years ago, crossed a broad marshy plain traversed by an arm of the river Marombas. His progress here was much impeded by devious winding trenches which followed the course of the stream, and occasionally lost themselves in it. At the time Herr Odebrecht could not understand the origin of these peculiar trenches, but is now inclined to believe that they were the work of the "Minhocao."

About fourteen years ago, in the month of January, Antonio José Branco, having been absent with his whole family eight days from his house, which was situated on one of the tributaries of the Rio dos Cachorros, ten kilometres from Curitibanos, on returning home found the road undermined, heaps of earth being thrown up, and large trenches made. These trenches commenced at the source of a brook, and followed its windings; terminating ultimately in a morass after a course of from 700 to 1,000 metres. The breadth of the trenches was said to be about three metres. Since that period the brook has flowed in the trench made by the "Minhocao." The path of the animal lay generally beneath the surface of the earth under the bed of the stream; several pine trees had been rooted up by its passage. One of the trees from which the Minhocao in passing had torn off the bark and part of the wood, was said to be still standing and visible last year. Hundreds of people from Curitibanos and other places had come to see the devastation caused by the Minhocao, and supposed the animal to be still living in the marshy pool, the waters of which appeared at certain times to be suddenly and strangely troubled. Indeed on still nights a rumbling sound like distant thunder and a slight movement of the earth was sensible in the neighbouring dwellings. This story was told to Herr Müller by two eye-witnesses, José, son of old Branco, and a stepson, who formerly lived in the same house. Herr Müller remarks that the appearance of the Minhocao is always supposed to presage a period of rainy weather.

In the neighbourhood of the Rio dos Papagaios, in the province of Paranà, one evening in 1849 after a long course of rainy weather, a sound was heard in the house of a certain João de Deos, as if rain were again falling in a wood hard by, but on looking out, the heavens were seen to be bright with stars. On the following morning it was discovered that a large piece of land on the further side of a small hill had been entirely undermined, and was traversed by deep trenches which led towards a bare open plateau covered with stones, or what is called in this district a "legeado." At this spot large heaps of clay turned up out of the earth marked the onward course of the animal from the legeado into the bed of a stream running into the Papagaios. Three years after this place was visited by Senhor Lebino José dos Santos, a wealthy proprietor, now resident near Curitibanos. He saw the ground still upturned, the mounds of clay on the rocky plateau, and the remains of the moved earth in the rocky bed of the brook quite plainly, and came to the conclusion that it must have been the work of two animals, the size of which must have been from two to three metres in breadth.

In the same neighbourhood, according to Senhor Lebino, a Minhocao had been seen several times before. A black woman going to draw water from a pool near a house one morning, according to her usual practice, found the whole pool destroyed, and saw a short distance off an animal which she described as being as big as a house moving off along the ground. The people whom she summoned to see the monster were too late, and found only traces of the animal, which had apparently plunged over a neighbouring cliff into deep water. In the same district a young man saw a huge pine suddenly overturned, when there was no wind and no one to cut it. On hastening up to discover the cause, he found the surrounding earth in movement, and an enormous wormlike black animal in the middle of it, about twenty-five metres long, and with two horns on its head.

In the province of São Paulo, as Senhor Lebino also states, not far from Ypanema, is a spot that is still called Charquinho, that is, Little Marsh, as it formerly was, but some years ago a Minhocao made a trench through the marsh into the Ypanema River, and so converted it into the bed of a stream.

In the year 1849, Senhor Lebino was on a journey near Arapehy, in the State of Uruguay. There he was told that there was a dead Minhocao to be seen a few miles off, which had got wedged into a narrow cleft of a rock, and so perished. Its skin was said to be as thick as the bark of a pine-tree, and formed of hard scales like those of an armadillo.

From all these stories it would appear conclusive that in the high district where the Uruguay and the Paranà have their sources, excavations, and long trenches are met with, which are undoubtedly the work of some living animal. Generally, if not always, they appear after continued rainy weather, and seem to start from marshes or river-beds, and to enter them again. The accounts as to the size and appearance of the creature are very uncertain. It might be suspected to be a gigantic fish allied to *Lepidosiren* and *Ceratodus*; the "swine's snout," would show some resemblance to *Ceratodus*, while the horns on the body rather point to the front limbs of *Lepidosiren*, if these particulars can be at all depended upon. In any case, concludes Herr Muller, it would be worth while to make further investigations about the Minhocao, and, if possible, to capture it for a zoological garden!

To conclude this remarkable story, we may venture to suggest whether, if any such animal really exist, which, upon the testimony produced by Fritz Müller, appears very probable, it may not rather be a relic of the race of gigantic armadilloes which in past geological epochs were so abundant in Southern Brazil. The little *Chlamydophorus truncatus* is, we believe, mainly, if not entirely, subterranean in its habits. May there not still exist a larger representative of the same or nearly allied genus, or, if the suggestion be not too bold, even a last descendant of the Glyptodonts?

SUN-SPOTS AND DECLINATION RANGES

THE excellent article by Mr. Broun in a recent number of NATURE puts before us in a very clear manner the strong grounds that we have for believing in a true connection between sun-spots and terrestrial magnetism. If the argument were not already sufficiently powerful it might be yet further strengthened by bearing in mind that not merely do the most prominent inequalities march together in these two phenomena but the correspondence extends likewise to those waves of shorter period that ride as it were on the back of the longer ones. In a paper which is now before the Royal Society I have shown this intimacy of correspondence by comparing together the sun-spot and declination range records for the cycle extending from the minimum of 1855 to that of 1867. All the prominent sun-spot waves are reproduced by magnetic declination waves, the latter, however, invariably lagging behind the former.

Then with regard to the long period cycle under discussion I make it to begin for sun-spots with September 15, 1855, which was a minimum point, and to end with March 15, 1867, which was another minimum point. On the other hand the corresponding cycle for declination range begins with February 15, 1856, and ends with August 15, 1867. Thus the length of period is the same in both; the magnetic cycle lagging, however, five months behind that for sun-spots.

I may also mention that I am at present comparing together the Prague declination ranges with the sun-spot curve determined from Hofrath Schwabe's observations, and although the comparison is not finished, I believe that this lagging behind will form a prominent feature of the results. Further back than Schwabe we cannot go, as the sun-spot records are not sufficiently accurate for this kind of work.

I am not sure, however, that I quite agree with Mr. Broun when he says "no doubt the admission of the existence of a causal connection between the two phenomena is opposed to the hypothesis, which many other facts render wholly untenable, that the magnetic variations are due to the heating action of the sun."

As far as sun-spots and declination ranges are concerned, what are the facts regarding the connection between them? These are two in number. In the first place, all the considerable oscillations of the sun-spots are reproduced in the declination-ranges. Secondly, the reproductions in the declination-ranges lag, it appears, behind the corresponding sun-spot waves. This latter fact strikes me as being rather in favour of the view which regards declination-ranges to be (like temperature-ranges) in some way the result of an influence from the sun which is of the nature of an emanation or radiation. But I will not press the point except to remark that this and a host of other questions, some of them of great importance, must wait for their solution until we shall have obtained a sufficiently complete and continuous record of solar activity, and along with it an equally complete and continuous record of the radiant power of the sun.

From the observatories already established, we have a reasonable prospect of receiving good magnetical information, and there is abundance of meteorological activity, but it is nearly, if not absolutely, impossible, from the observations already made, to tell whether the sun be hotter or colder as a whole, when there are most spots on his surface. The sooner we get to know this the better for our problem.

BALFOUR STEWART

THE ISLANDS OF ST. PAUL AND AMSTERDAM

AS is now well known, a French expedition visited these islands towards the close of 1874 for the purpose of watching the transit of Venus across the sun on December 9 of that year. M. G. de l'Isle accompanied the expedition as botanist; Dr. Rochefort, with M. Vélain to assist him, were to look after the zoological and geological departments. M. Vélain, who was a pupil of Prof. Lacaze-Duthiers has just published, in the *Archives de Zoologie Expérimentale et Générale* (tome 6, 1877), a most interesting account of these islands and their fauna, with, in addition, a very detailed account of the collections of shells made. We are indebted to the extreme kindness of M. Vélain for the excellent illustrations which accompany this notice, which are taken from the original memoir.

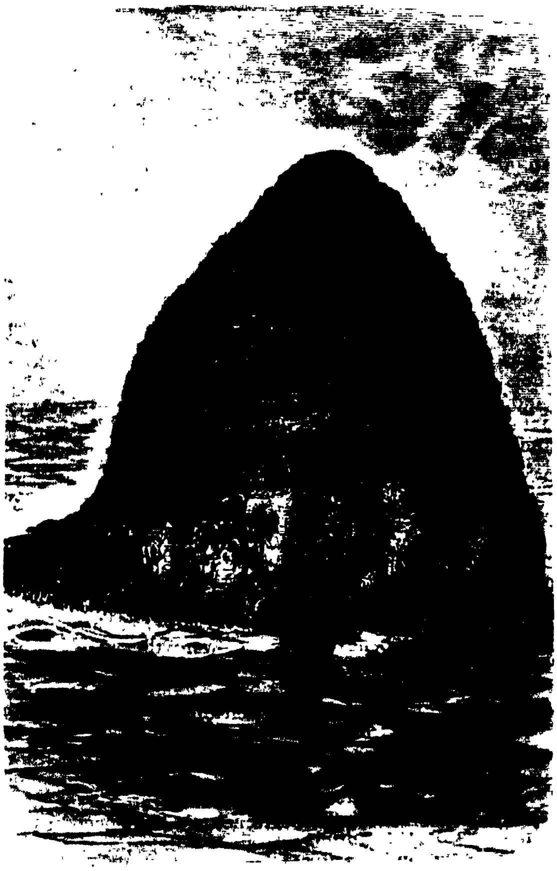

Fig. 1.—Ninepin Rock.

If the reader wishes to fix the exact position of these curious islands he has only to trace along the line of lat. 40° S., and about mid-way in the Southern Ocean between the Cape of Good Hope and Melbourne, near long. 80° E., he will find them.

Their discovery has been claimed by the Dutch and the Portuguese. Placed just in the grand ocean route for all vessels leaving the Cape for Australia or China, they were doubtless, despite their isolation, long known. The history of our knowledge of them from 1522 to the present day is well, though briefly, written by M. Vélain.

The *Novara* called at St. Paul in 1857, and stayed for fourteen days, and we are indebted to Hochstetter for an excellent account of the geology of the island, though the weather was so bad at the time that the collections made were not numerous.

In June, 1871, the English frigate *Megæra* was wrecked on this island and most of the 400 souls that were aboard her had to reside on it for over three months.

On September 30, 1874, the members of the Transit of Venus expedition landed on St. Paul and spent thereon over three months.

Both the islands are essentially volcanic. In 1696 when van Vlaming visited St. Paul, the vast crater occupied its central part, and was above and quite isolated from the sea, and it seems to have been even thus in 1754, but at present the sea flows freely into it, and at the place of communication there is a depth of upwards of six feet. It attains a height of about 250 metres and its contour line is not much more than five nautical miles. A little to the north of the entrance to the crater where the sea has broken in there is a wonderful pinnacle of basaltic lava, which receives the name of the Ninepin rock (Fig. 1). The rocks composing it are trachitic, of a compact texture, but more or less zoned. These rocks, full of silex, and poured forth in great measure under the sea, exhibit still the traces of the energetic alterations which they underwent, not only at the moment of their emission, but also after their complete solidification, for they have been traversed since their formation in every way; not only numerous fissures forced up by the impetuous escape of gaseous emanations but by the force of geysers, which latter considerably increased the amount of silex on the rock, and this so much so that the walls of such fissures through the trachytic rock are formed of a very able solid enamel of silex which is rarely hollow, and all the alkalies have totally disappeared. A microscopical examination shows, amid a highly developed amorphous paste, crystals of felspath, and pyroxene, with notable quantities of silex, amorphous (opal) or crystalline (tridymite); but the lavas of different periods of eruption seem to differ in their compositions.

A wonderful core of basalt columns is to be seen at the little North Island (Fig. 2) which consists of little else than columns, though many of them are now thrown down. Some of the more compact of the lavas present a more or less picturesque outline, as can be seen at Hutchinson Point (Fig. 3), towards the south-east of the island. Their endurable and adhesive glissades could alone furnish such needle-shaped projections as would be capable of resisting the extreme and never-ceasing violence of the seas that beat on them. Along with the basaltic lavas, there will be found here and there on their upper surfaces little cones of scoriæ thrown up from little supplementary volcanoes; sometimes these will be found here and there quite isolated, at other times they will be found forming a ring as it were around the principal crater. They form a record of the fact that long after the great original outburst that formed this island there were numerous smaller eruptions, and that the source of volcanic power endured for a considerable time.

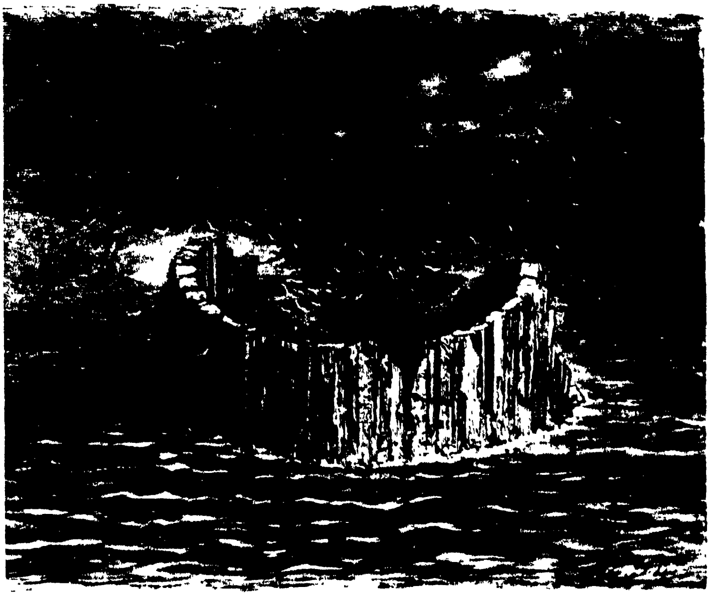

Fig. 2.—North Island.

Although at the period of Lord Macartney's visit (1793), Dr. Gillian remarks that there were spots on the island too warm to walk on, yet there is not a trace of recent volcanic action to be now felt or seen, except in the interior of the crater. M. Vélain informs us that the botanical collections made will be fully described by Dr. de l'Isle (from fifty to fifty-five species, not counting algæ, were found), and that the rich and large collections of marine animals, including fish, Crustacea, Echinoderms, Ascidians, Hydro-

Fig. 3.—Lava Cliffs—Hutchinson Point.

zoa, and Alcyonaria, will be described under the superintendence of Prof. Lacaze Duthiers.

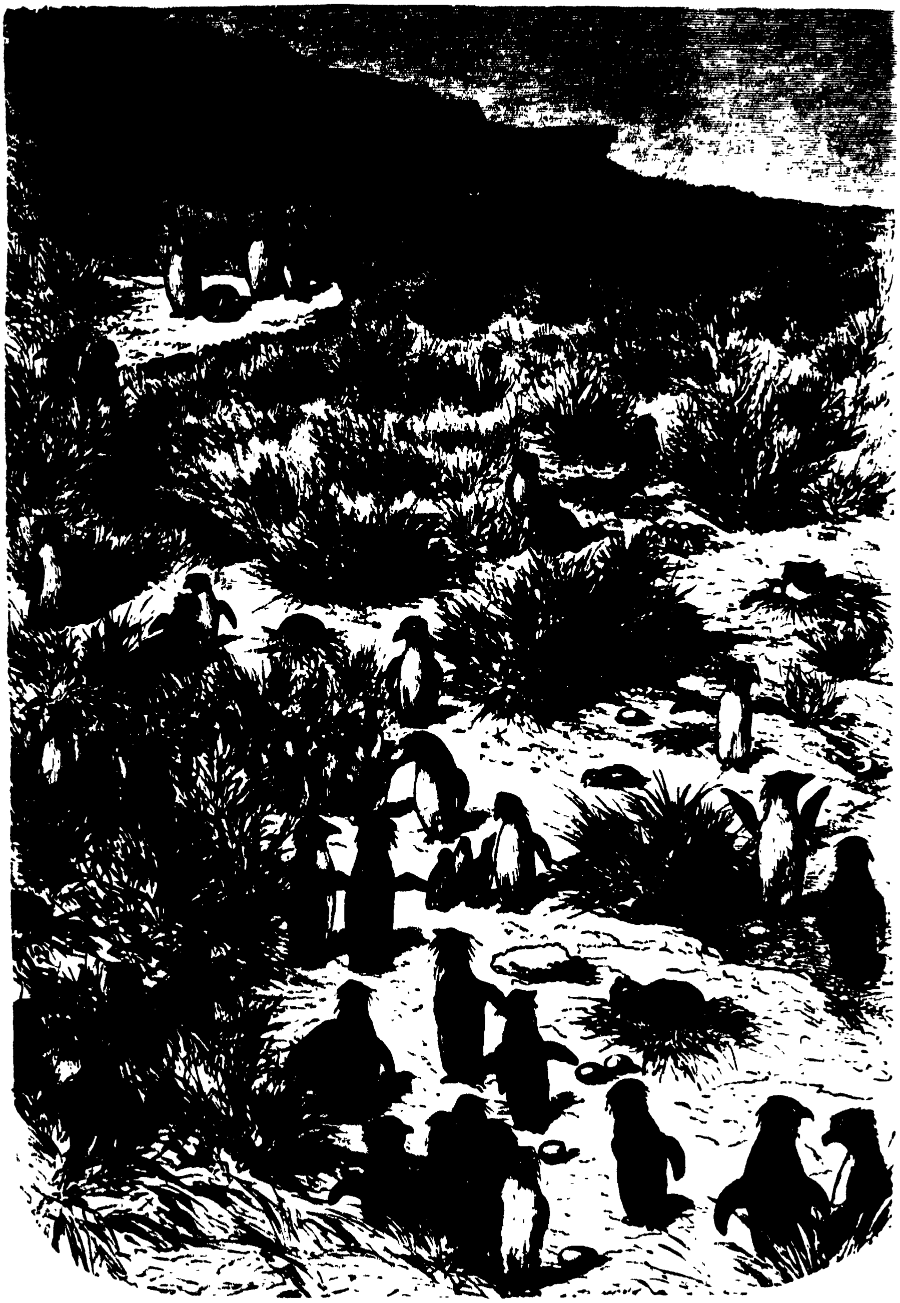

Fig. 4.—Penguins and Young.

In this present memoir M. Vélain himself gives some most graphic descriptions of the birds that were met with. The little swift seen by Dr. Scherzer, of the *Novara*, did not turn up, nor were any land birds met with, but the aquatic birds abounded in immense numbers. Among these were the following :—*Diomedea exulans*, *D. fuliginosa*, *D. melanophrys*, *D. chlororhyncha*, *Ossifraga gigantea*, *Procellaria capensis*, *P. cinerea*, *P. hæsitata*, *Puffinus æquinoctialis*, *Stercorarius antarcticus*, *Prion vittatus*, *Sterna melanoptera*, and last, but by no means the less important, *Eudyptes chrysolopha*. The history of these last birds, though often told, is ever strange, and seems always new. In the month of September these penguins began to lay; there were two colonies of them, the larger of which contained millions of the birds; the ground seemed alive with them. But it would be impossible, in a few words, to tell the reader all that M. Vélain has here written about their village life and their infant-schools; about their wonderful powers of diving; nor do we wonder that he looks back with no regret to the pleasant hours he spent in their midst, and we quite agree with him that such intelligent birds can't merit that nasty English word "stupid."

The accompanying illustration (Fig. 4) will give some slight notion of a nesting station of these interesting birds. At the time of the arrival of the expedition (October) the birds were preparing to hatch; each pair kept entirely to themselves; each nest had two eggs, large, nearly round, of a dirty white colour, but marked here and there with a few russet spots. Both birds partook of the cares attendant on the incubation, and took turn about on the nest. The bird off duty would at once make for the sea, faithfully returning at the appointed time, and never failing to waddle direct to its own nest, though no human being could see a difference between the thousands that were strewn about. Sometimes the whole camp of birds would have to be traversed ere the nest sought for would be gained, and a bird trying to make a short cut would be sure to be attacked by those whom it disturbed, for they are not at all tolerant of one another, and in this they also prove that they are not stupid, for surely neither stupid people nor stupid birds ever quarrel. On M. Vélain arriving in their midst, they would one and all set up an immense and beyond measure stunning cry, but soon they would calm down, and seem not to mind his presence. The incubation lasted for five weeks. The little ones made their appearance covered all over with a fine close down, and looked like balls of fine grey-coloured wool. They soon got tired of the comforts of their nests, and began to assemble together with their little brothers and sisters of the same colony in large infant schools, which are presided over by some of the sedate old birds. Many times a day, at stated intervals, they are fed, the other portions they spend in sleeping and talking, and a little fighting. Space will not permit us to refer to many curious details about their swimming lessons.

M. Vélain's description of the molluscs of Saint Paul is an important contribution to science; the new species are well illustrated on four plates. As was to be expected, there are forty species of Gasteropods to but nine of Acephala, and there is but a single Brachiopod; no land-shells seem to have been found. The cuttle-fish taken are not enumerated, but one gigantic ten-armed species was often alluded to by the fishermen, and at last, as if to prove their assertions true, one morning, after a great storm, a specimen thereof was thrown ashore, and fortunately was at once photographed; unfortunately only its head, arms, and pen could be preserved. The generic name of Mouchezis (after the commander of the expedition) has been proposed for it. Probably it comes near to Steenstrup's Architeuthis, which it resembles in size, by its having circular-shaped suckers, which were ornamented by a row of fine horny denticulations and by their arrangement on the arms, but from which it differs by the singularly shortened form of the short arms, which presented quite the appearance of having been abruptly truncated instead of running out to a more or less tapering point as in most cephalopods; and then the inferior termination of the dorsal ossicle is quite unlike that described by Steenstrup in his genus. *Mouchezia Sancti-Pauli* measured from the tip of its longest arms to the end of the body, upwards of twenty-two feet. A species of Ommastrephes swarmed in the adjacent sea and seemed to be the chief food of the penguins.

E. PERCEVAL WRIGHT

NOTES

names those groups of plants only comparable to that of Linnæus. His services to science were recognised by the Royal Society in his election as a foreign member in 1875.

THE funeral service of M. Claude Bernard took place at Paris, at the public expense, on Saturday, February 16, at St. Sulpice, in presence of an immense assembly. The interment took place at Père-la-Chaise. The chief mourners were MM. Bardoux, the Minister of Public Instruction, Dumas and Bertrand, Perpetual Secretaries of the Academy of Sciences, Fizeau, President, Mezières, Chancellor of the Academy of Sciences, M. Paul Bert, who is filling the chair of Claude Bernard at the Jardin des Plantes, and Laboulaye. These gentlemen delivered addresses at the grave, which will be published in the *Comptes Rendus* and official papers.

FROM the last report of Dr. Dohrn, the director, we notice that the zoological station at Naples has developed a most remarkable degree of activity, and is becoming a valuable centre of biological research. By the generosity of the Prussian Government it has been provided with a small steamer, and the uninterrupted expeditions in this vessel have secured to the laboratories an enormous and most varied stock of material for research. Dr. Dohrn has carefully organised a plan for the systematic examination of the entire fauna of this part of the sea, to be accompanied by exhaustive description. The literary portion of the work will consist of elaborate monographs on all the families and species represented in the Gulf of Naples. They will not be prepared by the members of the station only, but it is hoped to procure the assistance of all familiar with this special department, and the contributions can be in English, French, German, or Italian. Two monographs on the Ctenophoræ and Balanoglossi will appear during the present year, and arrangements have been made for the speedy preparation of eleven others. These will all be based, in regard to nomenclature and classification, on a work shortly to appear under the title, "Prodromus Faunæ Mediterraneæ," which will contain a complete abstract of the literature on this subject up to the present time. The details of anatomical and embryological investigation will form the leading feature of the whole work.

THE Radicals in the French Chamber cannot be accused of opposition to the claims of science. We notice that in a late session a member of the extreme left proposed an amendment to the budget of instruction, which provided for the appropriation of 30,000 francs for an expedition to California to observe the next transit of Mercury, 40,000 for the continuation of the explorations in Northern Africa, where it has been proposed to admit water from the Mediterranean, and 100,000 to enable the Abbé Debès to make a journey across Africa from Zanzibar to the Congo. As the appropriation was granted, we may hope soon to see the latter portion of it cause the appearance of a new rival of Stanley, for the Abbé has had, like Livingstone, invaluable experiences as a missionary, which will enable him to enter upon the undertaking with great promises of success.

THE Astronomical Section of the French Academy has been summoned by the Minister of Instruction to nominate two candidates for the vacant position of the late M. Leverrier.

IN Parisian scientific circles Prof. Charles Friedel is mentioned as the probable successor to the place in the Chemical Section of the Academy rendered vacant by the death of Victor Regnault.

A NEW Archæological Institution at St. Petersburg was opened on January 27 last. The director and founder of the Institution, M. N. W. Katcholoff, delivered the inaugural address, in which he pointed out the importance of the archæological investigation of the great Russian empire, and the great support the Institution will offer to students of Russian archæology. He also announced that the Russian Government had permitted the publication of a special organ of the Institution the first part of which would shortly appear, and would contain valuable details dating from the time of Alexander I.

A NEW Society of Ethnography, Archæology, and History is to be founded at the University of Kazan.

THE Annual Archæological Congress of France will take place this year at Mans and Laval, beginning at the former place on May 20 and closing at the latter on May 28.

AN interesting course of lectures has been inaugurated in connection with the new museum of ethnography at Paris, which is well adapted to heighten the value of these extensive collections. Nearly every afternoon is appropriated to a discourse by some well-known *savan* on topics illustrated in the museum. Among the subjects for the remainder of the month we notice "The Industrial Products of Central Asia," by M. de Ujfalvy; "The Ancient Mexicans," by Dr. Hamy; "The Lambaquis of Brazil," by M. Wiener; "Feathers, and their Employment among Savage Tribes," by M. Milne-Edwards; "Peruvian Ceramic," by M. Wiener; "Exploration of the Sahara," by Commander Roudaire; "The Useful Plants of Equatorial America," by M. André, &c. Like most of the lectures in Paris, these are free to the public.

THE works for establishing the monster captive balloon at the Tuileries have begun in the court of the old palace. The Municipal Council of Paris voted the demolition of the ruins at its last sitting. It is proposed by the Corporation that the demolition be completed for the opening of the Paris Exhibition.

NEWS from Berlin states that Signor Martinelli has started from Athens for Olympia in order to take the casts of the sculptures recently excavated, particularly of the Apollo of the western front of the building and of the Hermes of Praxiteles. The exhibition of the Olympian casts at Berlin will be deferred until Signor Martinelli has finished his work. All the other casts are now complete at the Campo Santo, near the Berlin Dome. The second volume of the "Ausgrabungen von Olympia," with thirty-five photographic plates, is in course of publication.

SIR JOHN LUBBOCK'S Ancient Monuments' Bill passed the second reading on Tuesday. We hope that it will this session pass successfully through the final stage.

MR. W. ACKROYD writes to us with reference to the mechanism of the ear and the bearing it may have on the structure and use of the telephone. In man the drum is inclined to the axis of the external ear passage at about an angle of 46°, and may be less or more in other animals. Mr. Ackroyd thinks that here we are taught that the best disposition of a membrane designed to receive aërial impulses is that of a less or greater angle to the resonating cavity in which it is placed, the value of this angle probably depending upon the depth and form, &c., of such cavity, points only to be ascertained by experiment. In communicating these ideas the other day to Mr. Wilson, of the Physical Laboratory, South Kensington, he stated that Mr. Newth, of the Chemical Laboratory, had found that his telephone worked best when he spoke into it in a slanting direction. Mr. Ackroyd thinks that telephonists will receive many valuable ideas from the study of the comparative morphology of the external auditory apparatus as Bell did by studying the action of the human tympanic membrane.

WE learn from the Annual Report of the Russian Hydrographical Department, just appeared, that during the year 1876 the officers of the department took soundings in the Baltic Sea and along the Finnish shores for 1,100 miles, in the Gulf of Bothnia for 2,130 miles, in Lake Onega for 870 miles, and in the Black Sea for 2,170 miles.

THE Central Physical Observatory at St. Petersburg has issued its report for 1876, containing meteorological observations made during that year at ninety-eight stations, according to the international regulations. An appendix gives the results of the hourly observations made at Moscow during the last fourteen years.

WE are glad to announce the opening at St. Petersburg of a new hygienic society. It is divided into five sections: Biology; Statistics and Epidemiology; Hygiene of towns, manufactures, and public buildings; Hygiene of schools; and Hygiene of food. Prof. Zdekauer is president of the Society, and among the members are some of the most prominent names in the St. Petersburg University and Academy of Sciences.

SINCE January 5 a new *Allgemeine Technikerzeitung* has been appearing at Leipzig (Schäfer) every week. It is a well-written serial and contains frequent reports of the latest progress of the natural sciences from a practical point of view.

THE German Emperor has presented a most valuable collection of arms and weapons to the Ethnographical Department of the Royal Museum of Berlin. The collection was made by Herr Erdmann, the German Consul at Samarang (Java), and consists of weapons from Java, Sumatra, Borneo, Celebes, Flores, Amboina, and other islands of the great Archipelago.

EARTHQUAKES are reported from the Lower Danube on January 31 at 4.30 A.M. It is also announced that the cities of Lima and Guayaquil, in South America, have suffered terribly from recent shocks.

FOR the first time since 1840 Lisbon has been visited by snow. Besides 1840 the years 1837 and 1839 were characterised by this phenomenon.

IN studying the vibrations of solid bodies, M. Dubois has recently got some interesting effects by use of water mixed with vermilion. If this be put on the branches of a tuning-fork which is vibrated, striæ are produced, the vermilion settling in the grooves of the liquid, and giving a figure. Operating first with tuning-forks, then with sounding-tubes and vibrating-plates, M. Dubois arrived at these two laws:—1. Two sounds produced by different instruments give the same separation of striæ, if these sounds are of the same pitch. 2. Two sounds of different pitch give striæ inversely proportional to the numbers of vibrations of the sounds. In the case of the pipes (which were open), a small band of paper carrying the liquid charged with vermilion was fixed with wax at the open part. The vibration of the air immediately produced striæ. The blast being adapted to give a grave fundamental sound, a certain set of equidistant divisions was produced; then on blowing to sound the octave, these divisions remained, but a second set of intermediate lines appeared.

AT p. 113, vol. xvi. of NATURE we drew attention to the gratuitous distribution of a little pamphlet entitled "Notes for Observations of Injurious Insects." This was issued under the auspices of a few well-known entomologists with a view of obtaining any information, however varied, on the habits of the insects and the conditions of the crops most conducive to their increase. It will be remembered that the late Mr. Andrew Murray took a lively interest in the question of the destruction of the crops by insect pests, and read a paper on the subject before the Society of Arts, so that the returns which have been received in answer to the above-mentioned pamphlet and which are now embodied in the form of a report will be specially interesting to entomologists and valuable to cultivators. It is satisfactory to find that some well-known pests were not so abundant in some districts last year as they were in the preceding year; thus we are told that near Isleworth but little injury was noticed amongst the onions from the fly, *Anthomyia ceparum*, though in 1876 it was very destructive, which indeed was the case generally in the western suburbs of London, and perhaps also in other parts. Two remedies are recommended for warding off the insects; one by scattering amongst the plants some pulverised gas-lime, and the other by watering with the liquid from pig-sties. The clouded yellow butterfly (*Colias edusa*) was, it seems, "the great appearance of the year," and was first seen near Dumfries early in June, and across the south of England it was generally observable from June till October. The frequent death of the larvæ when feeding on various clovers and trefoils is mentioned as a point of interest relatively to its permanent settlement, as also the great difference in the quantity of the sexes noticed at various stations which may be followed by coincident variety of appearance next year. The report is published by Mr. T. P. Newman, Botolph Lane, Eastcheap, from whom we believe copies may be obtained. Every information on the subject will also be supplied on application to the Rev. T. A. Preston, The Green, Marlborough, Wilts, E. A. Fitch, Esq., Maldon, Essex, or Miss E. A. Ormerod, Dunster Lodge, Spring Grove, Isleworth.

THE St. Petersburg University has addressed a note to the Ministry of Public Instruction requesting that the necessary steps be taken for the preservation of any valuable manuscripts which may be found in the Turkish towns occupied by Russian troops. Valuable manuscripts were preserved in this way from destruction in the War of 1829, and important manuscripts have already been discovered in the mosques of Tirnova.

A SMALL Japanese "blue" book comes to us in the shape of a report by the department of Public Hygiene on some of the mineral waters of the country and the uses to which they may be put. Japan seems to contain a great variety of such waters.

AT the meeting of the Musical Association on February 4 a paper was read by Mr. D. J. Blaikley, "respecting a Point in the Theory of Brass Instruments." The necessary difference in form between such instruments and conical tubes was pointed out, and a new experimental method for determining the positions of the nodal points in tubes, especially applicable to such as are of varying section, was shown. As an instance may be given a conical tube open at both ends and of the pitch C 512 vib. The node is nearer the small than the large end of the tube, and by sinking one end in water and holding a fork of the pitch of the tube over the other, the exact position of the node is shown by the level of the water when the tube is giving its maximum resonance.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus*) from India, presented by Lieut-Col. Fielden; a Grivet Monkey (*Cercopithecus griseo-viridis*) from North-east Africa, presented by Mr. E. H. Lockley; a Garden's Night Heron (*Nyctia gardeni*) from South America, presented by Mr. Henry Bottrell; three Chimpanzees (*Troglodytes niger*) from West Africa, deposited; a Black-faced Spider Monkey (*Ateles ater*) from East Peru, a Collared Peccary (*Dicotyles tajaçu*) from South America, a Globose Curassow (*Crax globicera*) from Central America, a Black-footed Penguin (*Spheniscus demersus*) from West Africa, a Hey's Partridge (*Caccabis heyi*) from Arabia, purchased.

ON COMPASS ADJUSTMENT IN IRON SHIPS [1]

I.—*New Form of Marine Azimuth and Steering Compass with Adjuncts for the complete Application of the Astronomer-Royal's Principles of Correction for Iron Ships.*

THIRTY-EIGHT years ago the Astronomer-Royal showed how the errors of the compass, depending on the influence experienced from the iron of the ship, may be perfectly corrected by magnets and soft iron placed in the neighbourhood of the binnacle. Partial applications of his method came into immediate use in merchant steamers, and within the last ten years have become universal not only in the merchant service, but in the navies of this and other countries. The compass and the binnacles before you are designed to thoroughly carry out in practical navigation the Astronomer-Royal's principles. The general drawback to the complete and accurate realisation of plans for carrying out these principles heretofore, has been the great size of the needles in the ordinary compass which renders one important part of the correction, the correction of the quadrantal error for all latitudes by masses of soft iron placed on the two sides of the binnacle, practically unattainable; and which limits, and sometimes partially vitiates, the other chief part of the correction, or that which is performed by means of magnets placed in the neighbourhood of the compass. Five years ago my attention was forced to this subject through my having been called upon by the Royal Society to write a biographical sketch of the late Archibald Smith, with an account of his scientific work on the mariner's compass and ships' magnetism, and I therefore commenced to make trial compasses with much smaller needles than any previously in use; but it was only after three years of very varied trials, in the laboratory and workshop, and at sea, that I succeeded in producing a mariner's compass with the qualities necessary for thoroughly satisfactory working in all weathers and all seas, and in every class of ship, and yet with small enough needles for the perfect application of the Astronomer-Royal's method of correction for iron ships. One result at which I arrived, partly by lengthened trials at sea in my own yacht, and partly by dynamical theory analogous to that of Froude with reference to the rolling of ships, was that steadiness of the compass at sea was to be obtained not by heaviness of needles or of compass-card, or of added weights, but by longness of vibrational period [1] of the compass, however this longness is obtained. Thus, if the addition of weight to the compass-card improves it in respect to steadiness at sea, it is not because of the additional friction on the bearing-point that this improvement is obtained; on the contrary, dulness of the bearing-point, or too much weight upon it, renders the compass less steady at sea, and, at the same time, less decided in showing changes of the ship's head, than it would be were the point perfectly fine and frictionless, supposing for the moment this to be possible. It is by increasing the vibrational period that the addition of weight gives steadiness to the compass; while, on the other hand, the increase of friction on the bearing-point is both injurious in respect to steadiness, and detrimental in blunting it or breaking it down, and boring into the cap, and so producing sluggishness, after a short time of use, at sea. If weight were to be added to produce steadiness, the place to add it would be at the very circumference of the card. My conclusion was that no weight is in any case to be added, beyond that which is necessary for supporting the card; and that, with small enough needles to admit of the complete application of the Astronomer-Royal's principles of correction, the length of period required for steadiness at sea is to be obtained, without sacrificing freedom from frictional error, by giving a large diameter to the compass-card, and by throwing to its outer edge as nearly as possible the whole mass of rigid material which it must have to support it.

In the compass before you (Fig. 1), these qualities are given by supporting the outer edge of a card on a thin rim of aluminium, and its inner parts on thirty-two silk threads or fine copper wires stretched from the rim to a small central boss of aluminium, thirty-two spokes, as it were, of the wheel. The card itself is of thin strong paper, and all the central parts of it are cut away, leaving only enough of it to show conveniently the points and degree-divisions of the compass. The central boss consists of a thin disc of aluminium, with a hole in its centre, which rests on the projecting lip of a small aluminium inverted cup mounted with a sapphire cap, which rests on a fixed iridium point (Figs. 2 and 3).

Eight small needles from 3¼ inches to 2 inches long, made of thin steel wire, and weighing in all fifty-four grains, are fixed like the steps of a rope ladder on two parallel silk threads, and slung from the aluminium rim by four silk threads or fine copper wires through eyes in the four ends of the outer pair of needles.

The weight of the central boss, aluminium cup, and sapphire cap, amounts in all to about five grains. It need not be more for a 24-inch than for a 10-inch compass. For the 10-inch compass the whole weight on the iridium point, including rim, card, silk threads, central boss, and needles, is about 180 grains. The limit to the diameter of the card depends upon the quantity of soft iron that can be introduced without inconvenient cumbrousness on the two sides of the binnacle to correct the quadrantal error. If, as sometimes may be advisable in the case of a pole or masthead compass, it be determined to leave the quadrantal error uncorrected, the diameter of the compass-card may be anything from 12 to 24 inches, according to circumstances. A 24-inch card on the new plan will undoubtedly have less frictional error or "sluggishness" for the same degree of steadiness than any smaller size; but a 12-inch card works well even in very unfavourable circumstances, and it will rarely, if ever, be necessary to choose a larger size unless for convenience to the steersman for seeing the divisions, whether points or degrees. You see hanging over the table, from the roof, one of my 12-inch pole-compasses. Specimens of 15-inch and 24-inch pole-compasses have also been made. The last-mentioned may be looked at with some curiosity, as being probably the largest compass in the world. It will no doubt be properly condemned as too cumbrous for use at sea, even in the largest ship, but there can be no doubt it would work well in a position in which a smaller compass would be caused to oscillate very wildly by the motion of the ship. The period of the new 10-inch compass is in this part of the world about forty seconds, which is more than double the period of the A card of the Admiralty standard compass, and is considerably longer than that of the ordinary 10-inch compass, so much in use in merchant steamers. The new compass ought, therefore, according to theory, to be considerably steadier in a heavy sea than either the Admiralty compass or the ordinary 10-inch compass, and actual experience at sea has thoroughly fulfilled this promise. It has also proved very satisfactory in respect to frictional error; so much so that variations of a steamer's course of less than half a degree are shown instantly and surely, even if the engine be stopped, and the water perfectly smooth.

---

[1] Report of paper read to the Royal United Service Institution, February 4, by Sir Wm. Thomson, LL.D., F.R.S., P.R.S.E., Professor of Natural Philosophy in the University of Glasgow, and Fellow of St. Peter's College, Cambridge. Revised by the Author. [The Council of the U.S.I. have kindly permitted us to publish Sir W. Thomson's paper in advance, and have granted us the use of the illustrations.—ED.]

[1] The vibrational period, or the period (as it may be called for brevity) of a compass, is the time it takes to perform a complete vibration, to and fro, when deflected horizontally through any angle not exceeding 30° or 40°, and left to itself to vibrate freely.

With the small needles of the new compass, the complete practical application of the Astronomer-Royal's principles of correction is easy and sure: that is to say, correctors can be applied so that the compass shall point correctly on all points, and these correctors can be easily and surely adjusted at sea, from time to time, so as to correct the smallest discoverable error growing up, whether through change of the ship's magnetism, or of the magnetism induced by the earth, according to the changing position of the ship. To correct the quadrantal error I use a pair of solid or hollow iron globes placed on proper supports, attached to the binnacle on two sides of the compass. This mode is preferable to the usual chain boxes, because a continuous globe or spherical shell of iron is more regular in its effect than a heap of chain, and because a considerably less bulk of the continuous iron suffices to correct the same error. When in a first adjustment in a new ship, or in a new position of a compass in an old ship, the quadrantal error has been found from observation, by the ordinary practical methods, it is to be corrected by placing a pair of globes in proper positions according to the following table:—

When the quadrantal error has been thus once accurately corrected, the correction is perfect to whatever part of the world the ship may go, and requires no adjustment at any subsequent time, except in the case of some change in the ship's iron, or of iron cargo or ballast sufficiently near the compass to introduce a sensible change in the quadrantal error. The vast simplification of the deviations of the compass effected by a perfect correction of this part of the whole error has not, as yet, been practically appreciated, because, in point of fact, this correction had rarely, if ever, in practice, been successfully made for all latitudes. The pair of large needles of the compass ordinarily used in merchant ships does not, as has been shown by Capt. Evans and Archibald Smith, admit of the correction of the quadrantal error in the usual manner, without the introduction of a still more pernicious error, depending on the nearness of the ends of the needles to the masses of chain, or of soft iron of whatever kind, applied on the two sides of the compass to produce the correction. The Admiralty standard compass, with its four needles proportioned and placed according to Archibald Smith's rule, is comparatively free from this fault: but even with it, and still more with the stronger magnets of the larger compasses of merchant ships, there is another serious cause of failure depending on the magnetism induced in the iron correctors by the compass needles, in consequence of which, if the quadrantal error is accurately corrected in one latitude, it will be found over-corrected in high magnetic latitudes, and under-corrected in the neighbourhood of the magnetic equator. The new compass was specially designed to avoid both these causes of failure in the correction of the quadrantal error; and experiment has shown that with it the correction by such moderate masses of iron as those indicated in the preceding table, is practically perfect not only in the place of adjustment, but in all latitudes.

When once the quadrantal error has been accurately corrected

gradually changed, so as always to balance the ship's magnetic force as it alters, whether by gradual loss of her original magnetism through lapse of time, or by the inductive influence of the earth's vertical magnetic force coming to zero, and then becoming reversed in direction when a ship makes a voyage from the northern to the southern hemisphere. The not carrying out of this essential part of his plan, whether through no method or no sufficiently convenient method of adjustment having been hitherto provided, has undoubtedly taken away much of the credit among many practical men to which the Astronomer-Royal's method is justly entitled. I have, therefore, introduced into the binnacles provided for my compass, when it is to be used in iron ships, a complete system of adjustable correctors for perfectly correcting the error of the compass for every position of the ship's head when she is on even keel, and a vertical adjustable magnet below the compass, for correcting the heeling error (more properly speaking, a magnet, which is vertical when the ship is on even keel, and which shares the inclination of the ship when she heels over to either side).

An objection which has often been made to the use of correctors at all, and particularly to the use of correctors for a standard compass, is that they conceal the actual state of the ship's magnetism, and that readjustment of the correctors at sea leaves the navigator without means of judging, when he returns from a foreign voyage, how much of the changed error found on readjustment in port depends on changes which have been made in the correcting magnets, and how much on changes of the ship's own magnetism. This objection I meet by providing that at any moment my correctors can be removed or set to any degrees of power to which they may have been set at any time in the course of the voyage, and again reset to their last position with perfect accuracy. The appliances for changing the adjustment are under lock and key, so that they can never be altered, except

even dangerous. It always renders needlessly tedious and cumbrous the process of readjustment by the adjuster in port, and it leaves the captain of the ship practically no other method of readjustment at sea than removing the magnets altogether, or taking them out of their cases and replacing them in inverted positions. The Astronomer-Royal himself pointed out that his correcting magnets should be mounted in such a manner that their distances from the compass can be

corrector may at once be altered to the prop

it. Of course the officer performing the adjustment will satisfy himself of its correctness by a second observation. The objection of "delicacy of manipulation," and the difficulty of carrying it out, except by a professional adjuster, of which so much has been said, is entirely done away with when adjustable correctors, with scales thus accurately graduated, are provided with the binnacle.

The binnacles before you are of two kinds adapted to the two different methods given by the Astronomer-Royal for correcting the semi-circular part of the error; one, the square one, for correcting, by two sets of magnets, fore-and-aft and thwart-ship respectively; the other, the round one, for correcting by a single magnet, or group of bars equivalent to a single magnet, placed under the centre of the compass with its magnetic axis in the proper direction to balance the whole disturbing force on the compass due to that part of the ship's magnetism which is unchanged when she is put on different courses in the same magnetic latitude. The two sets of instructions, in the two printed pamphlets before you, explain sufficiently, for the two binnacles, the arrangements of the magnetic correctors in the two cases, and how to use them in practice.

The principle in each case is easily understood. In the system employed in the square binnacle the whole constant force, due to the part of the ship's magnetism which remains constant when the ship is put on different courses, is regarded as being replaced by three constant "component" forces in the direction of three lines, at right angles to one another—one fore-and-aft, one thwart-ship, and the third perpendicular to the deck. The fore-and-aft component is balanced by the fore-and-aft correcting magnets, the thwart-ship component by the thwart-ship magnets, and the component perpendicular to the deck by the heeling corrector, which is a bar-magnet, adjustable to the proper height, in a line perpendicular to the deck, through the centre of the compass and of the binnacle.

In the round binnacle the component perpendicular to the deck is balanced by a heeling corrector, just as in the square one; but, instead of considering separately two components parallel to the deck, their resultant or the single component parallel to the deck, which, with the component perpendicular to the deck, constitutes the whole force, is balanced by a single magnetic force parallel to the deck. This force is obtained by turning the revolving corrector round the central axis of the binnacle, and raising it or lowering it until the proper direction and proper magnitude of force are produced.

One novel feature in the last binnacle is the way in which, by aid of the guide-ring graduated to logarithmic cosecants, and the vertical scale graduated to equal proportionate differences of force, the adjustment to correct the compass on one course may be performed without disturbing its accuracy on another course on which it has been previously adjusted. The principle of this arrangement is most easily explained by aid of the mathematical notation of trigonometry, in connection with the annexed diagram (Fig. 4), in which O represents the compass-card, A, a point of the ship which was in the direction of the correct magnetic north, N, at the time of the first supposed adjustment, *ns*, the position of the axis of the revolving corrector set to correct the compass on that course, H the ship's head. We have (according to the notation of the instructions)—

$$\begin{aligned} HOA &= H, \\ nOH &= C; \\ \text{therefore, } nOA &= H + C. \end{aligned}$$

Now the correction on the first supposed course, if it did not annul the force due to the magnetism of the ship and correctors, reduced it to a force in the line OA. Hence the component perpendicular to OA due to the corrector must be kept unchanged in subsequent correction, so as not to disturb the adjustment for that first course. Let F be the magnitude of the force due to the revolving corrector. Its direction being O*n*, its component perpendicular to OA is equal to F sin *n*OA. Hence, if F be increased by raising, or diminished by lowering, the corrector, the angle *n*OA must be altered so that sin *n*OA shall vary inversely as F, or cosec *n*OA directly as F. In other words, $\dfrac{F}{\operatorname{cosec} nOA}$ must be kept constant, and, therefore, the difference between log F and log cosec *n*OA must be kept constant. When the guide-ring is placed according to Rule 2, Section 4, of the Instructions, the reading upon it is the value of log-cosec (H + C). The reading on the vertical scale is always proportional to the logarithm of F. Hence Rule 3 secures that the change of magnitude and direction of the correcting force does not vitiate the correction on the course H.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—An examination for the Burdett-Coutts Scholarship will be held in the University Museum, on Monday, March 11, and three following days, at 10 A.M., for the purpose of electing a scholar on that foundation. Candidates are requested to call on the Professor of Geology at 34, Broad Street, with certificates of their standing, and the consent of the head or vice-regent of their College or Hall, on Friday, March 8, between 4 and 5 P.M.

CAMBRIDGE.—The exhibition offered by the Clothworkers' Company, to non-collegiate students of the University, for proficiency in physical science, has been awarded to J. G. M'Cubbin, who was educated at the Manchester Grammar School. The exhibition is of the annual value of 50*l.*, and is tenable for three years. The next examination for a similar exhibition open to non-collegiate students who have not resided more than one term, or who have not commenced residence, will be held on July 15 and 17, in connection with the examination conducted by the Oxford and Cambridge Schools Examination Board. Intending candidates can obtain full information on application to the Rev. R. B. Somerset, censor of non-collegiate students, Cambridge.

GILCHRIST EDUCATIONAL TRUST.—A course of six Gilchrist Science Lectures for the People, will be delivered in the Bristol Athenæum, by members of the Council and Staff of University College, Bristol, as follows:—February 22, The Action of Heat, by S. P. Thompson, B.Sc., B.A.; March 5, Heat and the Steam Engine, by J. F. Main, B.A. Camb., D.Sc. Lond; March 12, The Ocean a Carrier of Heat, by W. L. Carpenter, B.A., B.Sc.; March 19, Heat within the Safety Lamp, by S. P. Thompson, B.Sc., B.A.; March 26, the Sun's Heat, by J. F. Main, B.A. Camb., D.Sc. Lond.; April 2, the Chemistry of Burning, by W. W. J. Nicol, M.A. The same course is to be given at Bath, Bridgwater, Trowbridge, and Newport (Monmouthshire).

THE BIRKBECK INSTITUTION.—The Lord Mayor has promised to preside at a meeting, to be held at the Mansion House on Wednesday afternoon, the 27th inst., at three o'clock, for the purpose of inaugurating a fund to provide the Birkbeck Institution with a building suitable to its large and important operations, and to enable it to take advantage of the many opportunities for further usefulness which are from time to time presented. As the Institution is doing such an important educational work amongst the young men and women of the metropolis, it is hoped that the friends of education will liberally assist the movement to accomplish so desirable an object. The number of students has been steadily increasing for some years past, and, notwithstanding alterations and extensions of the building, it is impossible any longer to accommodate those attending the Institution. Some indication of the work will be gained from the fact that 3,304 persons joined the Institution during the past term.

ST. PETERSBURG. The professors of the High School of Medicine for Ladies at St. Petersburg, among whom are many names well known in science, have addressed a petition to the Minister of Public Instruction, in which they claim for ladies who have completed their studies at the high schools, the same degrees as for men. They support their request by pointing out that the five years' theoretical and practical study at the ladies' school are quite as extensive as those pursued by male students, and rather more extensive in the department of female diseases; that the monthly and yearly examinations have always proved that the ladies possess a very thorough knowledge of their subjects, and finally, that during their service with the army in Roumania and Bulgaria, the ladies have given numerous and sufficient proofs of their high capacity for acting as surgeons.

FREIBURG.—The university is attended at present by 334 students, including 41 in the theological faculty, 70 in the philosophical, 76 in the legal, and 147 in the medical. It possesses a library of 300,000 volumes, and well-equipped scientific laboratories and collections, but fails of late years to rank among the influential German universities, partly on account of the rivalry of its neighbours, Tubingen, Heidelberg, and Strasburg.

WÜRZBURG.—The corps of instructors numbers at present 40 ordinary professors, 5 extraordinary professors, and 17 privat doc[illegible]n. The number of students, 947, shows a decrease of abo[illegible]50 on the past half year. On January 2 the 296th anniversary of the foundation of the university was celebrated, and an address delivered by the rector, Prof. Risch, on the national importance of the German universities and their relations to the empire. In the course of the address the Imperial Government was sharply criticised for having, with the exception of the ample provisions for Strasburg, utterly neglected the university system of the country, and failed to introduce the uniformity of management and many other reforms, the need of which is painfully felt since the formation of a united Germany. Prof. Sachs, the well-known botanist, has been raised into the nobility, possibly in recognition of his refusal of a flattering call to Berlin.

HANOVER AND AIX-LA-CHAPELLE.—The two large polytechnics in these cities show a striking diminution in point of attendance during the past year, a fact which would seem to show that the various technical branches in Germany are being overcrowded. Hanover is attended at present by 725 students and the instructors number 46. Aix-la-Chapelle has suffered a reduction of 200 students in comparison with 1876.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 17.—"New Determination of the Mechanical Equivalent of Heat," by J. P. Joule, LL.D., F.R.S.

An account is given by the author, of the experiments he has recently made, with a view to increase the accuracy of the results given in his former paper, published in the *Philosophical Transactions* for 1850. The result he has now arrived at, from the thermal effects of the friction of water, is, that taking the unit of heat as that which can raise a pound of water, weighed *in vacuo*, from 60° to 61° of the mercurial thermometer; its mechanical equivalent, reduced to the sea-level at the latitude of Greenwich, is 772·55 foot-pounds.

February 7.—"On the Comparison of the Standard Barometers of the Royal Observatory, Greenwich, and the Kew Observatory," by G. M. Whipple, B.Sc., F.R.A.S., Superintendent of the Kew Observatory.

Owing to certain statements having been circulated as to a large difference existing between the standard barometers of the above two chief meteorological establishments in this country, the Kew Committee decided to institute a direct comparison between them, by the conveyance of a number of instruments to and fro, several times between the two observatories.

The author accordingly did this, having made three extended experiments of this nature, details of which are given in the paper, the results being as follows:—

Mean difference from—

1st series of	[illegible]	comparisons.—Greenwich-Kew	[illegible] inch.
2nd ,,	144	,, ,, ,,	– [illegible]7 ,,
3rd ,,	72	,, ,, ,,	– [illegible]14 ,,
Final mean of	344	,, ,, ,,	0·0012 ,,

Certain experiments were also made to determine the necessary corrections to be applied to the Greenwich barometer on account of inequality of distribution of temperature around it. When these corrections are applied the difference between the two standards is reduced to 0·0001 inch, that is to say, the two instruments virtually agree.

In conclusion the author tenders his thanks to the Astronomer-Royal, for the facilities he afforded for the prosecution of the experiments, and to Messrs. Ellis and Nash for assistance they rendered.

Geological Society, January 23.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—J. Eunson, C.E., R. C. Forster, Walter Mawer, Richard H. Solly, and the Rev. Arthur Watts, were elected Fellows of the Society. The following communication was read:—On the secondary rocks of Scotland.—Part III. The strata of the Western Coast and Islands, by John W. Judd, F.R.S., F.G.S., Professor of Geology in the Royal School of Mines. The existence of scattered patches of fossiliferous strata, lying between the old gneissic rocks and the masses of tertiary lava in the Hebrides, has been known to geologists for more than a century. By Dr. Macculloch, who did so much for the elucidation of the interesting district in which they occur, these strata were referred to the lias; but Sir Roderick Murchison showed that several members of the oolitic series were also represented among them. Later researches have added much to our knowledge of the more accessible of these isolated patches of Jurassic rocks in the Western Highlands. During the seven years in which he has been engaged in the study of these interesting deposits, the author of the present memoir has been able to prove that not only is the Jurassic system very completely represented in the Western Highlands, but that associated with it are other deposits representing the carboniferous, poikilitic (permian and trias), and cretaceous deposits, the existence of which in this area had not hitherto been suspected; and by piecing together all the fragments of evidence, he is enabled to show that they belong to a great series of formations, of which the total maximum thickness could have been little, if anything, short of a mile. The relations of the scattered patches of mesozoic strata to the older and newer formations respectively, are of the most interesting and often startling character. Sometimes the secondary rocks are found to have been let down by faults, which have placed them thousands of feet below their original situations in the midst of more ancient masses of much harder character. More usually they are found to be buried under many hundreds, or even thousands, of feet of tertiary lavas, or are seen to have been caught up and inclosed between great intrusive rock-masses belonging to the same period as the superincumbent volcanic rocks. Occasionally the only evidence which can be obtained concerning them is derived from fragments originally torn from the sides of tertiary volcanic vents, and now found buried in the ruined cinder-cones which mark the sites of those vents. In some cases the mineral characters of the strata have been greatly altered, while their fossils have been occasionally wholly obliterated by the action of these same igneous forces during tertiary times. In every case the survival to the present day of the patches of secondary rocks can be shown to be due to a combination of most remarkable accidents; and a study of the distribution of the fragments shows that the formations to which they belong originally covered an area having a length of 120 miles from north to south, and a breadth of fifty miles from east to west. But it is impossible to doubt the former continuity of these secondary deposits of the Hebrides with those of Sutherland to the north-east, with those of Antrim to the south, and with those of England to the south-east. From the present positions of the isolated fragments of the mesozoic rocks, and after a careful study of the causes to which they have owed their escape from total removal by denudation, the author concludes that the greater portion of the British Islands must have once been covered with thousands of feet of secondary deposits. Hence it appears that an enormous amount of denudation has gone on in the Highlands during tertiary times, and that the present features of the area must have been, speaking geologically, of comparatively recent production—most of them, indeed, appearing to be referable to the pliocene epoch. The alternation of estuarine with marine conditions, which had, on a former occasion, been proved to constitute so marked a feature in the Jurassic deposits of the Eastern Highlands is now shown to be almost equally striking in the Western area; and it is moreover pointed out that the same evidence of the proximity of an old shore-line is exhibited by the series of cretaceous strata in the west. The succession and relations to one another of the series of deposits, now described as occurring in the Western Highlands, is given in the following table:—

Miocene Volcanic and Intervolcanic Rocks.

UNCONF

		Maximum thicknesses feet
Cretaceous.	1. Estuarine clays and sands with coal	20 +
	2. White chalk with flints (zone of *Belemnitella mucronata*)	10 +
	3. Estuarine sandstones with coal	100

Carboniferous strata (coal-measures).

UNCONFORMITY.

Old Gneiss Series and Torridon Sandstones.

Although no traces of the upper oolite or the neocomian formations have as yet been detected in the Western Highlands, yet it is argued that when we consider how enormous has been the amount of denudation, and how singular the accidents to which all the existing relics of the secondary period have owed their escape from total destruction, we cannot but regard it as a most rash and unwarrantable inference to conclude that no deposits belonging to those periods were ever accumulated within the district under consideration. The carboniferous strata of the Western Highlands have been detected at but a single locality; and even there, being exposed in a series of shore reefs that are only occasionally well displayed, can only be studied under favourable conditions of tide and wind. They consist of sandstones and shales with thin coaly seams, and their age is placed beyond question by the discovery in them of many well-known plants of the coal-measures, including species of *Lepidodendron*, *Calamites*, *Sigillaria*, and *Stigmaria*. The poikilitic strata consist of conglomerates and breccias at the base, graduating upwards into red marls and variegated sandstone, which contain concretionary limestones and occasional bands of gypsum. These strata have not as yet, like their equivalents in the Eastern Highlands (the reptiliferous sandstone of Elgin and the Stotfield rock) yielded any vertebrate remains. They were evidently deposited under similar conditions with the beds of the same age in England, and are not improbably of lacustrine origin. The Jurassic series presents many features of very great interest. The infralias is better developed than is perhaps the case in any part of the British Islands; and in the district of Applecross a series of estuarine beds, containing thin coal-seams, is found to be intercalated with the marine strata. The lower lias, in its southern exposures, presents the most striking agreement with the equivalent strata in England, but when traced northwards exhibits evidence of having been deposited under more littoral conditions; the lower division (lias α, Quenstedt) is represented by a great thickness of strata; while the upper (lias β) is absent or rudimentary. The middle lias is grandly developed, and consists of a lower argillaceous member and an upper arenaceous one, the united thickness of which is not less than 500 feet. The upper lias singularly resembles in the succession of its beds, and its palæontological characters, the same formation in England. The inferior oolite is formed by series of strata varying greatly in character within short distances, and betraying sufficient signs of having been accumulated under shallow-water conditions. Above the inferior oolite we find a grand series of estuarine strata, partly arenaceous and partly calcareo-argillaceous; and this is in turn covered conformably by an unknown thickness of blue clays with marine fossils of middle Oxfordian age. At the very lowest estimate, the Jurassic series of the Western Highlands could not have had a thickness of less than 3,000 feet! The cretaceous strata of the Western Highlands, though of no great thickness, are of surpassing interest. They consist of two marine series alternating with two others of estuarine origin. At the base we find marine deposits of upper greensand age, strikingly similar to those of Antrim, but in places passing into conglomerates along old shore lines. Above the upper greensand beds occur unfossiliferous sandstones, in which thin coal-seams have been detected, and these are in turn covered by strata of chalk, converted into a siliceous rock, but still retaining in its casts of fossils (*Belemnitella*, *Inoceramus*, *Spondylus*, &c.), and in its beautifully preserved microscopic organisms (*Foraminifera*, *Xanthidia*, &c.) unmistakable proofs of its age and the conditions of its deposition. Above this representative of the highest member of the English chalk there occur argillaceous strata with coal-seams and plant-remains which are perhaps the equivalent of younger members of the cretaceous series, not elsewhere found in our islands, or, it may be, they must be regarded as belonging to periods intermediate between the cretaceous and tertiary epochs. It is greatly to be regretted that these cretaceous deposits of the Western Highlands are so unfavourably displayed for our study as to present scarcely any facilities for the collection of their fossils; for these, if found, might be expected to throw a flood of light on some of the most obscure palæontological problems of the present day. Although the comparison and correlation of the secondary strata of the Highlands with those of other areas, and the discussion of the questions of ancient physical geography thereby suggested, are reserved for the fourth and concluding part of his memoir, the author takes the opportunity of making reference, in bringing the present section of his work to a close, to several problems on which the phenomena now described appear to throw important light. In opposition to a recent speculation which would bring into actual continuity the present bed of the Atlantic and the old chalk strata of our island, he points to the estuarine strata of the Hebrides as demonstrating the presence of land in that area during the cretaceous epoch. He also remarks on the singular agreement of the conditions of deposition of both the silurian and cretaceous strata of the Scottish Highlands and those of the North American continent. But he more especially insists on the proofs, which we now have, that the Highlands of Scotland, as well as the greater part of the remainder of the British Islands, were once covered by great deposits of secondary strata, and that the area has been subjected to enormous and oft-repeated denudation. He dwells on the evidence of the vast quantities of material which have been removed subsequently to the mesozoic and even to the miocene period, and he maintains the conclusion that many, if not all, of the great surface-features of the highlands must have been produced during the very latest division of the tertiary epoch, namely the pliocene.

Mathematical Society, February 14.—Lord Rayleigh, F.R.S., president, and subsequently Mr. C. W. Merrifield, F.R.S. vice-president, in the chair.—The following communications were made:—On a general method of solving partial differential equations, Prof. Lloyd Tanner.—On the conditions for steady motion of a fluid, Prof. Lamb (Adelaide), (particular cases of the conditions were given by Stokes in the Cambridge *Phil. Trans.* for 1842).—On a property of a four-piece linkage and on a curious locus in linkages, Mr. A. B. Kempe.—On Robert Flower's new mode of computing logarithms (1771), Mr. S. M. Drach.—On the Pluckerian characteristics of the modular equations, Prof. H. J. S. Smith, vice-president, F.R.S.—Mr. Drach also exhibited drawings of tricircloids made some thirty years since for Mr. Perigal.

Royal Microscopical Society, February 6.—Anniversary.—H. C. Sorby, president, in the chair.—The report of the Treasurer was submitted to the meeting.—The report of the Council stated that the library and instruments of the Society were in a satisfactory condition, and obituary notices of deceased Fellows, Dr. Bowerbank and Dr. Henry Lawson, were read by the Secretary. Messrs. Glaisher and Curties having been appointed scrutineers, a ballot for officers and council for the ensuing year took place with the following result:—President, H. J. Slack; Vice-presidents, Dr. L. S. Beale, Dr. C. T. Hudson, Sir John Lubbock, Bart., and Mr. H. C. Sorby; Treasurer, Mr. J. W. Stephenson; Secretaries, Mr. Chas. Stewart and Mr. Frank Crisp; Council, Mr. John Badcock, Mr. W. A. Bevington, Dr. R. Braithwaite, Mr. Chas. Brooke, Mr. C J. Fox, Dr. W. J. Gray, Mr. E. W. Jones, Dr. Matthews, Mr. S. J. McIntire, Dr. John Millar, Mr. Thos. Palmer, and Mr. F. H. Ward; Assistant-secretary, Mr. Walter W. Reeves. The retiring president then delivered his annual address, which chiefly treated of the results of his investigations into a method of obtaining the refractive indices of minerals.

SNAKE POISON

EVERY now and again the British public is horrified by accounts of the famines which periodically carry off myriads of our fellow-subjects in India, but comparatively few have the least idea of the enormous destruction of human life which occurs there from the ravages of wild animals and venomous snakes. In a most interesting lecture recently delivered at a meeting of the Society of Arts by Sir Joseph Fayrer, the lecturer estimated the loss of life at no less than 20,000 human beings and 50,000 head of cattle annually. Wild animals destroy most of the cattle, but venomous snakes kill more human beings than all the wild animals put together. The bites of these reptiles caused the death of 17,000 persons, and over 3,000 cattle in the year 1875, and these figures very probably understate the facts, as the returns upon which they are based are incomplete. The desirability of obtaining an antidote to snake poison is thus evident, and many attempts have been already made to discover one. Another has been added to the already numerous investigations on this subject by Mr. Pedler, who has lately published the results of his research in a paper read before the Royal Society. Before proceeding to seek for the antidote, he endeavoured to analyse the poison chemically, and thus discovered several facts of great interest. The venom of snakes seems to contain very much the same proportion of solids at all times, even under such different climatic conditions as during the wet and dry seasons. It may be kept for two or three months without alteration, but if preserved for a year or eighteen months, it becomes insoluble, and, to a great extent, loses its poisonous qualities. Its composition is very like that of albumen, and, indeed, the dried poison, which looks very like gum arabic, contains about sixty per cent. of albumen, and only forty per cent. at most of the poisonous principle. By the use of solvents, Mr. Pedler endeavoured to separate a crystalline principle, such as Lucien Bonaparte affirmed to be present in the poison of the rattlesnake. His attempts were unsuccessful, and he therefore tried to obtain it by dialysing the poison through parchment paper. Part of the poison dialysed, and part did not. On evaporating the fluid inside the dialyser, the residue formed a gummy mass, with a poisonous action. The water outside the dialyser also gave a similar result, but in it a few crystals could be detected. It was, if anything, rather more poisonous than the ordinary virus. He did not succeed, however, in obtaining any very definite crystalline substance. Ammonia, which has lately been highly recommended as an antidote in snake poisoning, he found, as did Fontana two hundred years ago, to be useless, and indeed its addition to the poison before injection seemed really to hasten death.

Some organic poisons may have their physiological action greatly altered by changing their chemical constitution. Thus strychnia has its action completely altered by combination with iodide of methyl, so that instead of producing convulsions, it causes complete paralysis, like curara. At the same time its deadly power is greatly diminished, and it occurred to Mr. Pedler that the poisonous properties of cobra virus might be diminished in a similar way. On testing this supposition, he found it to be correct, as the poison, after digesting with ethylic iodide, took five times as long to kill an animal as fresh cobra poison would have done. Hydrochloric acid also diminished the activity of the virus, and platinum chloride had a still more powerful action. This salt seems to combine with the poisonous principle of cobra virus, forming with it a yellow amorphous precipitate, which is very insoluble in water, and which has little or no poisonous action. This result of the action of platinum chloride on cobra virus out of the body is most satisfactory; but this apparent antidote has not the same power when the poison has once entered the system. When the poison is injected under the skin and the platinum chloride is injected shortly afterwards into the same spot, death appears to occur even more quickly than when no antidote whatever is used, the second injection seeming to drive the poison before it and to cause it to act more rapidly. When the platinum chloride, however, is injected at the same point, but somewhat more deeply than the virus, so that in passing inwards the poison might come in contact with the platinum, life is considerably prolonged. If a short time elapses between the injection of the poison and that of the platinum, death ensues, even though the interval be only one or two minutes. It would thus seem that when the platinum chloride is brought directly into contact with the poisonous principle of the cobra venom it renders it insoluble and prevents its poisonous action, but that it is not a physiological antidote, and will not counteract the deadly action of the virus after it has once entered the circulation. It may be useful as a local application, but cannot be regarded as an antidote. Every means hitherto tried of counteracting the effects of cobra venom has thus proved ineffectual. Artificial respiration, proposed by Sir Joseph Fayrer and Dr. Lauder Brunton, gave fair promise of success, and by its use the heart may be kept beating for many hours. Indeed in one case an animal apparently dead for many hours has been partially revived by it, yet on no occasion has a fatal issue ever been averted by its use. The experiment just mentioned was performed by a commission appointed by the Indian Government, at Sir J. Fayrer's suggestion, to examine into the modes of preventing death from snake bite. A dog was bitten one afternoon by a water snake, and apparently died about three o'clock. Artificial respiration was at once commenced, and the heart continued to beat, but the animal seemed to be perfectly dead, and the limbs no longer responded to electrical stimuli. Early next morning, however, an alteration took place. The limbs again answered to electricity, voluntary movements occurred, and the eyelids closed not only when the eye was touched with the finger, but when the hand was simply brought near it. This showed that the animal could see the approaching hand, and closed its eyes in order to protect them from the expected touch. The dog seemed to be in a fair way to recovery, but about noon it began to get worse, and finally died at three o'clock on the second day, twenty-four hours after its first apparent death. Whether a combination of artificial respiration with other appliances may yet enable us to prevent death altogether, is a question which can only be determined by a continuance of those experiments which led to the use of artificial respiration alone. But however valuable such a method as this may occasionally be in saving the lives of English officers, government officials, or persons living within reach of skilled assistance, and who might otherwise be doomed to certain death from the bite of a cobra, it is obvious that it is too complicated to be of much service to the numerous natives who are bitten in localities where no other assistance can be had than that of their comrades, equally ignorant with themselves. If any great diminution is to be effected in the frightful mortality annually resulting from the bites of venomous snakes in India, the remedies must either be so simple and easy of application that they can be used by the most ignorant, or the snakes must be destroyed. The best instructions yet given for the treatment of persons bitten by poisonous snakes are contained in Sir Joseph Fayrer's magnificent work on "The Thanatophidia of India." He recommends that a tight ligature be applied to the limb above the bite, that the bitten part be cut out as quickly as possible, and that the wound thus left be cauterised with a hot coal or hot iron, or touched with nitric or carbolic acid, while brandy or ammonia should be administered internally. Even this treatment, simple though it be, requires knowledge, as well as instruments and skill, which the majority of the natives do not possess. Sir Joseph Fayrer therefore recommends that in every police station and public place plain directions should be printed and hung up, and that at all such places a supply of whipcord, a small knife, a cautery iron, and a bottle of carbolic or nitric acid should be kept, as well as a supply of liquor ammonia for internal administration. But, as Sir Joseph Fayrer says, although comparatively little is to be expected even from this rational mode of treatment, much may be anticipated from prevention, and it is to be effected by making known the nature and appearance of the venomous as distinct from the innocent snakes, and by offering rewards (to be judiciously distributed) for the destruction of the former. The differences between many of the non-venomous and the venomous snakes are not known to the natives, and it is important that a knowledge of such distinctions should be widely disseminated, not only that the venomous ones may be more easily recognised, and thus avoided or destroyed, but in order to prevent death or serious illness from sheer fright, which may frequently result from the bite of a non-venomous species. For this purpose it would be well if the pictures of the chief venomous snakes contained in Sir Joseph Fayrer's work, or cheaper but accurate lithographic copies of them, were displayed in every police station and public place throughout India. Rewards should be paid for the destruction of venomous snakes only, and if these pictures were exhibited in the way suggested there would be little or no excuse for any mistake, either on the part of the natives who killed the snakes, or the officers whose duty it would be to pay the reward. As to the amount of reward, and its mode of distribution, there should, he suggests, be a department, or branch of a department, with a responsible chief and subordinate agents, for whom certain rules should be laid down, to be observed steadily and without hindrance throughout the country, leaving much, as to detail, to the discretion of local authorities. If the destruction of venomous snakes and wild animals in India were intrusted to an officer such as controls the Thuggie and Dacoitee department, he considers that the result would in a few years be as good in the case of noxious animals as it has been in that of noxious men, Thugs and Dacoits.

THE BEETLES OF ST. HELENA

Coleoptera Sanctæ-Helenæ. By T. Vernon Wollaston, M.A., F.L.S. 8vo, pp. i.-xxv., 1-256, coloured plate. (London: Van Voorst, 1877.)

THIS, the last of its lamented author's valuable descriptive works on the geographical distribution of beetles (in personally collecting the material for which, it is to be feared that his physical exertions during a weak state of health induced the attack that ended recently in his death), must have been the most satisfactory to him, on account of the complete isolation of its subject, and his discovery of its most striking endemic fauna. The investigation of the *Coleoptera* of the Madeiras, Salvages, Canaries, and Cape-de-Verdes, with which his name will always be associated, had already resulted in a firm opinion that their peculiar beetle-types could not be satisfactorily referred to any geographical area now existing, but rather to some submerged Atlantic region, of which these groups are the modern representatives; and the results of his exhaustive work at St. Helena cannot have failed to materially strengthen this idea. Curiously enough, also, the most dominant type in this island is one to which Wollaston was always specially devoted, viz., the *Cossonidæ*, a little known family of weevils, whereof the inordinately numerous species here found, consisting of variations of some half-dozen forms occasionally developed to so marvellous an extent as to be almost ludicrous, amply justified his expression (*in litt.*) that he had "tumbled on his legs in this little oceanic preserve of the southern Atlantic."*

To any one interested in the faunæ of islands, no better conditions could be afforded than those found in St. Helena. Its vast distance from the nearest continents (nearly 1,200 miles from Africa, and 1,800 from South America) and, indeed, from the nearest island (Ascension, 700 miles), added to its complete severance by a fathomless depth at a mile and a half from its present coast-line, are premises of themselves suggesting the probability of abnormal resident forms; and the peculiar and very dense original vegetation of ebony, redwood, boxwood, *Psiadia*, asters, gumwood, cabbage-palms, tree-ferns, &c., would reasonably be expected to foster a development of special wood-feeding types, to the partial or entire exclusion of other groups. This development, anticipated by Wollaston from the eccentric species received in former years, is wonderfully illustrated by an analysis of the present work. In it, 203 species are recorded, and may probably be taken as very nearly exhausting the fauna, since the author captured, mounted, and examined (with a delicacy, precision, and care peculiar to himself) no less than 10,000 specimens. Of the difficulty attending the collection of such a mass in six months, the author affords an indication by his remark

(*Entomologists' Monthly Magazine*, xii. p. 252) that the net may be used over miles of grassy mountain-slopes without finding a single flower-frequenter, or anything approaching to it. Under these conditions, it is not to be wondered at that Mr. Melliss's account of the island, not long ago reviewed in NATURE, should, as not representing the work of an expert, have failed adequately to represent its peculiar coleopterous features. Of the 203 species above mentioned, fifty-seven have undoubtedly been conveyed to the island through various external media, and have since established themselves—many of them, indeed, being the regular followers of civilisation. Seventeen of the remainder possess doubtful claims to be considered indigenous, or even to have been taken in St. Helena at all. Of the 129 species left, and which may be safely deemed endemic, the distribution is highly eccentric. Whole groups, hitherto regarded as well-nigh cosmopolitan, are either entirely absent or barely represented; and one section, the weevils, is most unduly exaggerated, especially in one of its families. The missing divisions are water-beetles (both *Hydradephaga* and *Philhydrida*—the aquatic *Carnivora* and *Herbivora*), and *Longicornia*; and their absence is the more noteworthy, as proper natural conditions exist for both of them; and, as to the latter, other wood-feeders have inordinately increased and multiplied. The *Necrophaga* (a wide term, covering many families of universal distribution, including bone-, skin-, and fungus-feeders, acting as natural scavengers, and whereof we have, even in Great Britain alone, over 450 species) and *Trichopterygia* have each but a single representative. The *Pseudotrimera* (*Coccinellidæ*, &c.) and *Lamellicornia* can each only supply two. As to the former of these groups, Prof. Westwood has well observed that the inference is a want of *Aphides* and other plant-lice, on which lady-birds are the natural parasites; and on this point it would be interesting to know if the usual Homopterous vegetable-feeders are really wanting. If not indigenous they might be readily introduced; and, enumerating even the avowedly introduced *Pseudotrimera* in Mr. Wollaston's list, we find only four species to keep them down, since the *Corylophidæ* and *Erotylidæ* included in the group by the author cannot be reckoned. As to the Lamellicorns, the want of indigenous mammals would readily account for the absence of such of them as feed on the excreta of those animals (*two* only, both introduced, can be found; here Baron von Harold would assuredly perish of inanition!); but the mighty tropical clan, revelling in rotten wood, should surely in such a latitude, with the decaying forests of centuries for pabulum, have reared more than the miserable tale of four, whereof but two are autochthones! Next in number come the *Priocerata* and *Phytophaga*, respectively counting but three. The *Elateridæ* and *Anobiidæ*, essentially wood-feeders, are the only families of the first of these that provide indigenous species: how they have failed to produce more is incomprehensible. The fact of plant-feeding beetles being of the greatest scarcity has been already quoted from the author himself, and is equally unintelligible. The *Staphylinidæ* and *Heteromera* each supply six indigenous forms, the paucity of the latter being perhaps accounted for by the lack of those sandy wastes peculiarly affected by so many of its members. Next in importance come the *Geodephaga*, or land carnivorous beetles, whereof as many as fourteen (in fact all but one, and of them no less than eleven here described as new) are recorded. Here, again, the peculiarity of the island is emphasised, as the eleven new species, all of the genus *Bembidium*, depart widely from the shingle-, mud-, and marsh-frequenting habits of that vast and widely distributed genus, occurring as they do in the high central mountain ridges, and living inside the fibrous stems of rotten tree-ferns, an unexpected habitat as strange as that recorded in the Horatian lines:—

> "Piscium et summa genus hæsit ulmo,
> Nota quæ sedes fuerat columbis."

These arboreal Bembids have necessitated the creation of three new sub-genera, distinguished by abnormally minute eyes, want of wings, rounded outline, fossorial legs, and moniliform antennæ; and would alone have been sufficient to have stamped the fauna as *sui generis*.

Last, and most important, come the *Rhynchophora* or weevils, with no less than ninety-one representatives, more than two-thirds of the whole number. These again are represented in unusual proportions, the *Cossonidæ* numbering fifty-four, two-fifths of the entire fauna (we have in England but nine, out of 3,000 species), and the *Anthribidæ* twenty-six. The conclusion derived by the author is, that, as these weevils unquestionably represent the dominant autochthonous family, and all (but one) are of lignivorous habits, St. Helena may be pictured in the remote past as a densely-wooded island, in which they performed their natural functions of tree-destroyers among tree-ferns and *Compositæ* on a gigantic scale, unaided by the usual timber-eaters. The well-nigh complete destruction of indigenous trees in modern times has no doubt been accompanied by the loss of many a link in the aboriginal chain of these peculiar forms. Those that still survive are of such eccentric structure and facies that the creation of eleven new genera and forty new species has been necessitated for their reception in the present work, which, had it been the sole production of its author, would have effectually prevented his name from passing into oblivion.

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Oxygen in the Sun

ATTENTION having recently been directed by Dr. Schuster and Mr. Meldola, in connection with my discovery of oxygen in the sun, to the location of the oxygen, it may be of interest to allude to some experiments to determine the question by direct observation of the image of the sun spectroscopically. For this purpose I used a spectroscope furnished with a very fine grating on silvered glass given to me by Mr. Rutherfurd. This grating of 17,280 lines to the inch can be arranged to give a dispersion equal to twenty heavy flint glass prisms. The spectroscope was attached to my 12-inch Clark refractor, and I employed the full aperture of this telescope to produce an image of the sun on the slit. It did not seem practicable to use the spectroscope on the 28-inch Cassegrain reflector in this research, because the tremulousness of the air was usually too great, the image of the sun being magnified to five inches in diameter. Even with the 12-inch refractor the occasions suitable for a critical examination are rare.

In front of the slit I also brought the terminals of the secondary circuit of an induction coil, which were connected with a Leyden battery. The current through the primary wire of the Ruhmkorff was furnished by a Gramme machine. This arrangement permitted the production of a strong oxygen spectrum near the spectrum of the sun's limb.

The most obvious point to determine was whether the oxygen lines visible in the spectrum of the solar disc projected beyond the apparent limb of the sun as seen in the spectroscope; in other words, whether oxygen could be detected in the lower parts of the chromosphere. For this purpose I looked particularly at the bases of the prominences. I saw a large number of reversed lines, including some of the more delicate lines of Young's preliminary catalogue, but on no occasion could I be sure that the oxygen lines were seen outside of the limb. Of course, unless such an observation could be made in a perfectly tranquil atmosphere, certainty could not be attained. The experiments were terminated temporarily on account of getting my right arm caught in the engine, but they will probably be resumed next summer.

On examining Prof. Young's catalogue of chromosphere lines made at Sherman Station, in the Rocky Mountains, it appears that he does not note the great oxygen group near G, and as his observations were made with remarkable accuracy and care, this would tend to corroborate the view that the bright-line spectrum of oxygen as seen on the sun's disc must have its upper limit close to the apparent spectroscopic limb of the sun.

HENRY DRAPER

Observatory, Hastings-on-Hudson, New York, January 28

Brain of a Fossil Mammal

IN NATURE (vol. xvii. p. 222) is an account of some remarkable characters of the brain of *Coryphodon*, as determined by Prof. Cope, and recently published in the *Proceedings* of the American Philosophical Society, vol. xvi. It may interest some of the readers of NATURE to know that the subject had been previously investigated by the writer, who published a description and figures of the brain cast of *Coryphodon* in the *American Journal of Science*, vol. xi. p. 427, May, 1876, more than a year before the article above quoted appeared. Prof. Cope made no reference to my paper, although perfectly familiar with it. His figures moreover do not represent, even approximately, the brain of *Coryphodon*, owing to serious errors in his observations, which were based upon an imperfect specimen, as I have shown elsewhere (*American Journal of Science*, vol. xiv. p. 83). One of the most glaring of these errors is seen in the supposed olfactory lobes which, as figured, include no small part of the nasal cavities, and naturally add a very remarkable feature to this brain cast. The specimens from which my figures and description were taken are in excellent preservation, and are in the Yale College Museum, where they have been examined by Prof. Huxley and many other anatomists.

The attention called by NATURE to this paper of Prof. Cope's makes the present correction seem necessary for English readers, especially as the paper quoted is a typical one, illustrating the methods and work of its author. O. C. MARSH

Yale College, New Haven, Conn., February 7

Origin of Tracheæ in Arthropoda

IN NATURE (vol. xvii. p. 284) is a notice of a work by Dr. Palmen, of Helsingfors, on the morphology of the tracheal system. From the wording of the notice it appears as if the views of Dr. Palmen as to the origin of tracheæ from skin-glands, and as to the importance of Peripatus as an ancestral form of the Tracheata, were new to science. I was, to the best of my belief, the first to discover that Peripatus was provided with tracheæ; and in a paper on the structure and development of *Peripatus capensis*, published in the *Phil. Trans.* for 1874, I discussed the question of the origin of tracheæ, and put forward exactly similar views to those cited in your notice. These views have been adopted by Prof. Gegenbaur in his new edition of his "Grundriss der Vergleichenden Anatomie" (1878), in so far at least as that Peripatus is placed in a separate division of the Arthropoda, "the Protracheata." Haeckel, following Gegenbaur, supposed his Protracheata to have been provided with tracheal gills, but the diffuse arrangement of the tracheæ in Peripatus led me to conclude that the ancestral tracheata were terrestrial, and not aquatic, in habit, and that tracheal gills were comparatively late developments.

I am very glad to find that Dr. Palmen has arrived at similar results. Unfortunately, the place of publication of his treatise is omitted from your notice. It would be of value if you saw fit to append the reference as a note to the present letter.

Exeter College, Oxford H. N. MOSELEY

[Dr. Palmen's paper was published in Helsingfors.—ED.]

The "Phantom" Force[1]

III.

WHILE very clearly establishing that it is to the force urging a body that the potential energy which the body *has not*, but can have, must properly be assigned, and calling it very appropriately the "energy of tension,"[2] a very apposite remark (which I do not remember to have met with before) is added by "X" in his concluding paragraphs. The body could not command this "force-work" in any position unless it had *been put* into the proper position to command it; and the *actual energy* spent in putting it there *is the* "energy of tension" which, although forfeited to the force, *it can* reclaim. In this view it is not surprising that potential energy should have the same terms for its measurement as actual energy, since it is nothing but the actual energy which the body, or some agent operating upon it, has really lost; and if we pass from permanent forces to those ephemeral ones which physical agents can produce on an already existing arrangement of bodies, then, according to the existing configuration of the bodies when the force is generated, and in proportion to the "potential," or to the available statical energy developed, so is the work of the agent used to bestow this energy. In these cases of temporary "potentials" the actions are not actions at a distance, but through an intermediate medium, it may be strung with motion, and with permanent forces, which have absorbed the work applied to put the intervening medium, as it were, on the stretch, and to develop the ephemeral energy of tension. But we recognise this very clearly (as for instance in charging well-insulated electrical conductors) only in the rare cases of reversible arrangements. The fatigue and exhaustion which we soon feel when holding out at arm's length a heavy weight (although we do no work upon the weight) arises, for example (like that of a galvanic battery exciting an electro-magnet and supporting a heavy armature), from two causes, the first of which, the excitation of the magnet and armature, and the tightening of the muscles, or producing the requisite statical energy for the occasion, absorb but a small portion of the work. The main expenditure is "frittered away" (a most expressive description of the process, which I owe to Prof. Tait) in aimless and random paths as heat, by the wasteful process of electrical or muscular currents afterwards kept up to maintain the excitation.

I have thus far sketched out a general view of physics (one which is perfectly adapted to satisfy its general requirements), in which self-balancing actions and reactions, only depending in intensity on the distance between their centres are supposed to be permanently implanted in pairs of material particles, a special case, or fresh assumption regarding the general system of forces contemplated in the Newtonian theory of mechanics, which either may, or may not be the complete theory of their action, but which assists the mind very greatly, by giving them a mechanical explanation, in forming true and correct preliminary notions of the two leading laws of the great modern science of energy. And here I may take the opportunity to mention that my own views of the relationship of modern physics in its various mutually dependent branches to that famous foundation of mechanics which Newton laid (or perhaps I should rather say, since the supremacy of mechanics is by no means yet conceded, of the Newtonian basis of mechanics to modern physics) have been mainly imparted and completed by a perusal of the excellent little manual on "Matter and Motion" by Prof. J. Clerk

---

[1] Continued from p. 322.

[2] The term "statical energy" introduced by Sir W. Thomson (see a note in Prof. [illegible]'s "Sketch of Thermodynamics," p. 52), and now proposed (NATUR[illegible]. xvi. p. 521) by "W. P. O." to be substituted for the above, is of all the phrases yet used to denote it, the truest and simplest description of its real character. That it appertains to the force and not to the body is apparent both from this name and from the definition (which I have endeavoured to illustrate) that it is the "work" of the "agent," a property or possession of *that individual*, equal and opposite to, but *not the same* as its "net," or effected work.

Maxwell, reviewed by Prof. Tait in NATURE (vol. xvi. p. 119), a very moderate acquaintance with which has sufficed to remove from my mind all the doubts and perplexities which, without such assistance, must beset every cultivator of physics and mechanics attempting to take a comprehensive view of these two parallel sciences in their close relations to each other. The latter science especially, mutilated and deformed, and roughly scattered up and down in fragments, as we commonly find it represented, wears in general in our crude brains and in ordinary practice very much the same dismembered aspect which physics in its numerous subordinate branches presents to those who devote their attention especially only to some particular one of its departments.

But the new and comprehensive science of energy has, besides, its own special debatable region, in much the same way that mechanics has, although of an entirely different description; and however cheerfully we might consent, by basing all the propositions of mechanics (a perfectly possible proceeding, as has here been indicated) upon a system of permanent and reciprocal force-pairs, to include among the vicissitudes of force-action, besides its own clearly distinguishable phenomena, also (with countless impenetrably hidden fields of operation) all the known agencies of its more versatile and less easily definable kindred science of energetics, yet it can scarcely be regarded as immediately desirable, in the absence of sufficiently abundant proof, to make this assumption; nor is it perhaps expedient, on the new account just mentioned, to take it too readily for granted as a sound and simple basis of the leading laws of the new science, until the field of phenomena which the latter are framed to include is itself so clearly defined and circumscribed, as not to offer in its own relations and conditions objections to the course which may seem to contain in them anything which may prove to be insuperable, or which might very quickly lead to its abandonment.

To assert the principle of virtual velocities concerning the agent force, although we can voluntarily enlist the action of this agent in mechanical combinations, does not necessarily compromise our free will in any way, because the manner of enlisting this servant of our will cannot be definitely, and in a scientific point of view completely specified as the necessary form which the exercise of volition must take; and accordingly no natural law which completely binds and describes any force, can possibly describe and define also, as completely, the volition which produces it. But even if the volition concerned in producing a force were, as a cause, completely definable, and if we may assume that pure inductive science is capable immediately of so describing it in part, and of ultimately (in its indefinitely achieved development) reaching no partial or imperfect view of every process of volition, so as to be able with assigned actions of will to construct a perfectly unerring plan of all the operations of a Providence subjected to these conditions, and to trace without a single fault or discontinuity the whole current of consequent events belonging to them, yet it is evident that the result would lack an element of genuineness, of whose absence we should immediately be conscious as rendering it an inadequate and unauthentic representation of the operations of that perfect will and of that Divine Omnipotence, to whose purposes we owe the obedience and the entire subserviency of our wills in all our actions. This moral obligation of our actions springs from a side of our natures *truly* unseen, but to which we owe dictates of our actions as quick and spontaneous as those which come endorsed with reason to us from our natural senses. On the other hand, to suppose that reason will ever bridge the gap which divides inanimate from living agency, and will be able to register perfectly on her tablets (in the way just now supposed) every event of volition, is as visionary as to suppose her capable of apprehending and of taking a measurable account of the purposes of those actions which we hold to be inspired. But in the part which reason plays as a faculty given to us for learning wisdom and for seeking after and cultivating virtue from our cradles, in all the vicissitudes of life, there appears to be no break or interruption to its ownward progress, though its goals may be partly invisible and partly unattainable; and "new forces" in nature must evidently lie abundantly along its path. The "forces" of living beings, in particular, are inscrutable to it, and those of humanity at least must especially be so, for two reasons, a *moral*, as well as a vital or organic one, both differently descriptive of the ultimate constitution of our free will. If, therefore, there appears no ground (as I believe that Hirn's, and perhaps other experiments, have shown) for introducing an exception of living agents in the law of conservation of energy, perhaps the progress of physiology and of biological physics may also show that to make the same exception in the law of dissipation, or of the loss of availability of energy in every action, is equally incapable of substantiation could we see those forms of energy which we, and other living beings, make use of in apparently transgressing the generality of this law by partially restoring their availability to some very obvious forms of energy.

In this view of infinite progress of investigation, energy must keep its form of energy of motion, or of such energy converted into work of "agents;" and from what has been above described, it is not necessary that the work of these agents should be the energy thus abandoned in *a new kinetic* form. All the actions of an agent *can be imagined* to be consequences of special kinds of motion, but of what advantage it may be *to suppose it*, when in the midst of conceptions so distractingly profound and unapproachable as encircle the new science of energy, an agent as simple and intelligible as mechanical force is presented to our understanding as an example of what an agent of will and purpose may perhaps be like, it is very difficult to reflect upon and comprehend.

At the outset of this long-since-begun, and now quite-differently-concluded letter from what I contemplated, I proposed, in connection with Mr. Crookes' famous series of investigations (especially those last crowning points of his discoveries in which vacua so perfect were produced as fairly to eliminate the principal cause of rotation of the arms of a radiometer, originally recognised in the action of residual gas), to point out some means by which, in vacua so complete, the mode of action of force might possibly be elucidated by experiments. A beam of rays, bent and reflected, for example, so as to fall at grazing incidence from the right or left on a flat end, instead of on a vane of one of the arms of a very perfectly-exhausted radiometer, might be found to move it sensibly, and perhaps more distinctly, as the exhaustion reached its limit, in opposite directions corresponding to the directions from which the beam grazed the face, which it would be difficult to attribute to molecular impacts of the residual gas; and in the action of such an external, and to all ordinary perceptions quite uncounterpoised, force (supposing radiation really to produce it), a field of new discoveries relating to direct mechanical effects of the luminiferous ether would obviously present itself, which would be of the highest interest and consequence. But as regards the interpretation of any effects which might be observed, especially in connection with new views of the nature of potential energy which they might open out, I prefer now to refrain from offering any hints or suggestions, knowing that any inquiry which offers prospects of studying force under a new aspect, cannot be guided and directed beforehand, so as either to establish or confute any of the already well-proved laws of its action, but that in the broad principles which the science of energy presents for our consideration and development it could only be prosecuted as a new science, a new branch of general physics contributing something like its predecessors (heat, radiation, chemical action, electricity, &c., but *what* we should attempt in vain to picture to ourselves) in the capacious science of energy, as a new ascent towards that lofty pinancle to which in common with several other natural sciences energetics also proposes to raise itself in the end, to contemplate the Divine works of True Beneficence and to discern in the stately Temples of the Universe the allotted place of man.

These are some of the teachings of the radiometer which rose up before me when in an unguarded moment I asked myself the question: What change from the point of view of energy conservation would it introduce into our view of the experiment if, supposing that a force were found to actuate the vane of a radiometer, which was a direct effect of radiation, we were to sacrifice the integrity of Newton's third law of motion by assuming the existence of a new class of forces which act alone unaccompanied by any equal and opposite reaction?[1] The answer here must be that *if energy is still to be conserved* (that is to say, if we can *point out the source and destination* of all the work that is performed), *there must be a law in* these outer forces connecting them *with known physical agents* in such a manner that as much work is done upon them in any assigned change of configuration as is supplied by those physical agents in the change, and as the internal forces and other agents in the changing system also furnish by their action. (See Prof. Clerk Maxwell's definition of a "conservative system" in "Matter and Motion," p. 59, where the action of internal forces is excluded by supposing the system to

[1] Reaction is not meant here, of course, to imply Newton's imaginary "resistance of an acceleration;" but the real active tendency of some equal opposite force only, is meant to be understood.

return to its original configuration). In other words, we cannot suppose energy to be conserved unless we *connect the new forces by some fixed laws* with known and already determinate physical agents, and we must be content to regard the system *as non-conservative* until the necessary physical connection is assigned and introduced which will account for the free forces that we have observed, and will allow us to comprehend their action under the known laws of inanimate natural agency. This way of dealing with the work of "external forces" on a system which the new science of energy has devised, and shown to be the only one which in these cases can be generally employed, has perhaps contributed (but only by the unavoidable abstruseness and abstractness which belong to the new science itself) to invest with something of the appearance of a "phantom" and with an air of mystery, the character of force, and the laws of its operation as they have been universally studied in mechanics. But rightly regarded according to the simple principles of philosophical consistency and progress, which the new science of energy recognises in its probable extensions, there can be no doubt that it will really tend to establish more clearly than before the familiar notions of mechanics, and to open out fields of application of the time-honoured laws of motion and of force in unforeseen directions, in which their certainty and truth will continue to be felt as surely and to be described as simply now and hereafter, as they were in the days of Galileo and of Newton.

Newcastle-on-Tyne A. S. HERSCHEL

Faraday's "Experimental Researches"

MR. SILVANUS P. THOMPSON, of Bristol, has made, in NATURE (vol. xvii. p. 304) an inexplicable attack upon my issue of Faraday's "Experimental Researches in Electricity," 3 vols. 8vo. 1839–55, unwarranted by logic or facts.

Mr. Thompson ordered my issue, which is advertised as "*a perfect copy*" of Faraday's work, through a Bristol bookseller, to whom it was charged at the trade price of 36*s*. Mr. Thompson declined to ratify his purchase, and there the matter should have ended, as I would readily have cancelled the transaction with his agent.

Mr. Thompson says that I *profess* to supply *a perfect copy* of Faraday's "Experimental Researches," implying that my professions are deceitful. I am at a loss to understand his meaning, because the fact is that I can and do supply perfect copies.

The history of the book is as follows:—Faraday's "Experimental Researches," 3 vols., appeared in 1839 55, in 3 vols. 8vo, with plates, and in course of time two of the volumes fell out of print, which raised the market value of occasional copies to seven and eight guineas. Availing myself of the opportunity of buying from Mrs. Faraday the copyright and existing stock, I completed, by facsimile reprint, a small number of copies, as is plainly stated on the title-pages of vols 1 and 2. I alone possess the right to reprint the whole or a portion of the work.

It was at Mrs. Faraday's express wish that only such a reprint has been executed, and I was further advised to that course by eminent Fellows of the Royal Society. Mr. Thompson's innuendo of wilful deception is an infamous slander unworthy of a man of science.

I consider I deserve the thanks of all purchasers of Faraday's "Researches" for having invested my capital in the long dormant copyright of this work, and having thus put it in the power of students to obtain "perfect copies" at a moderate price.

Messrs. Taylor and Francis, the printers of the former edition, executed for me the reprint of the first two volumes (the stock of the original third volume not having been exhausted.) The original dates were preserved to show that no alterations had been made, and to preclude the notion, which Mrs. Faraday desired to avoid, that she had sanctioned a veritable new edition.

After this explanation I do not doubt that Mr. Thompson will see he has deceived himself, and I expect that he will apologise for his ill-advised attack upon my genuine and authorised re-issue, and admit that it is indeed a perfect copy of Faraday's great work.

BERNARD QUARITCH

Singing in the Ears

THIS consists of two or more continuous or alternating tones originating within the ear, very faint and sounding like a tea-kettle just beginning to boil, or a distant orchestra tuning. It is heard when there is undue pressure of the circulation in the head, as after long mental application, or upon hanging the head downwards. To my ear these tones bear constant musical relations to each other, and as the phenomenon bears directly on the theory of the *mechanism* of *audition*, its verification is a matter of importance.

Will the readers of NATURE who can observe it write me what are the *intervals* of *pitch* (*i.e.* thirds, fourths, octaves, fifths, &c.) between the different tones heard together or alternating?

Meteor

ABOUT 12.47 A.M. (Irish time) on Monday the 18th inst., I observed a brilliant meteor when looking north from the south side of Dublin. It resembled a bluish white ball with an apparent diameter of about one-fifth that of the moon, which was shining brightly at the time, and left behind it a continuous yellowish luminous train. When first sighted it appeared at an angular distance of about 15° from the polar star, and appeared to be in the constellation of the Dragon, about midway between the brilliant star of the constellation of Lyra and the polar star, somewhat below the line joining these constellations.

Its path was apparently a line about 5° from the vertical, and inclined from west towards east, and I lost sight of it when at an angle of 10° with the horizon by intervening buildings. Its brilliancy surpassed that of the moon, which at the time was bright enough to allow of distinguishing printed characters. It did not burst while in sight, and I heard no report.

Royal College of Science, Dublin H. HATFIELD

Eucalyptus

I have only just observed Dr. Calmy's letter in your impression of the 7th inst. (p. 283). The febrile attacks to which I alluded in NATURE (vol. xvii. p. 10) were sufficiently serious to incapacitate shepherds and stockmen for anything like continuous work for two or three weeks, and on some days the men were quite prostrated. The mosquito of which I spoke as not being banished by the presence of Eucalyptus is that species of Culex whose larval state is passed in water (the larvæ may even be seen in rain-water collected in decayed parts of trees), and I cannot call to mind a single place from which these pests were absent, trees being present. No doubt they may be carried many miles by the wind from their place of birth; but the real question is whether any species of gum so drains the land as to banish both mosquito and malaria by drying wet soil. If so, how is it that we find in Australia swamps which have existed for apparently an indefinite time, and do not look in the least likely to dry up, though the "blue" gum grows all round them, where the mosquito is rampant and malarious fever not by any means rare? I entirely agree with Dr. Calmy that the mosquito may be a "real danger to the rash traveller." One not acclimatised would suffer agonies among the mangrove swamps of Moreton Bay. I have had my own hands so paralysed by the poison that I could not close them without difficulty; and a new arrival, whom I took there on a duck-shooting expedition, was almost blinded, and became seriously ill for some days, though he was exposed to the attacks of the insects only a few hours. Whatever may be the case in Algeria or the Campagna, no one familiar with Australia will give the gum-trees there credit for having banished swamps, malaria, or mosquitos. Is not the Newfoundland mosquito of the pine forests to which Dr. Calmy alludes bred in water?

Telephone Experiments

THE following experiments with the ordinary small portable telephone may interest your readers.

Experiment 1. Connect a small strip of zinc by a thin covered wire to one of the binding screws of the instrument, and connect in the same way to the other binding screw a plate of metal with a rough edge; a saw does well. Place the end of the piece of zinc in the mouth, or hold it between moist fingers. Take a shilling between the fingers of the other hand and pass it along the teeth of the saw. The sound is clearly heard in the telephone. It instead of a shilling, a sovereign or a penny be used, the resul is much the same, but if a piece of zinc be substituted, the sound in the t[illegible]hone, if not lost, becomes very feeble.

Experiment 2. With the apparatus as before, let a number o persons, taking hand in hand, form a chain. At one end of thi chain the zinc is held, and at the other the shilling. When th saw is rubbed the sound is heard in the telephone so long as th hands are held, but on leaving go anywhere in the chain th telephone becomes silent. This experiment is successful wit eight persons, and no doubt would be with a larger number. The hands should be moistened.

These experiments show in a simple and striking way that in the telephone we have an instrument which is sensitive to very minute electric impulses. W. CARMAEL

24, Southampton Buildings, W.C.

ELIAS MAGNUS FRIES

BY the death of Fries, Sweden has lost one more of the line of eminent botanists whose labours have thrown a lustre so great upon Scandinavian science. Well versed in all domains of phanerogamic botany, and especially skilled in his native plants, it was amongst the cryptogams he spent the more active years of his long life. While lichenology owes to him valuable illustrations, fungology received at his hands a large element of its construction. In the acquisition, description, and systematic arrangement of the larger fungi he exhibited a zeal, a tact, and a perspicuity which seem to have left comparatively little to be done in later times, either by way of addition or improvement.

Elias Magnus Fries was born in Smaland on August 15, 1794. His father, pastor of the church at Femsjo, was an ardent and accomplished botanist. As there were no boys of his own age whom the young Fries could make companions, he constantly accompanied his father in his walks, and was in his earliest years made intimate with all the flowering plants of a district diversified by forest, mountain, marsh, and river. About the age of twelve he lighted upon an especially brilliant Hydnum, and was then first incited to the study of the Agarics and their allies, that abound in his native land more than in any other region of Europe. Before he left his school at Wexio he knew, and had given temporary names to, nearly 400 species. In 1811 he entered the University of Lund, where he had Schwartz, Agardh, and Retzius as his teachers; and in 1814 was chosen Docent of Botany. In this year he published his "Novitiæ Floræ Suecicæ," first part, the second part following in 1823. In 1815 appeared his "Observationes Mycologicæ," the first important result of his fungological researches. In the following year, dissatisfied with the method of Persoon, he began to construct an entirely new system. As a first fruit he wrote his "Specimen Systematis Mycologicæ," a tract of a few pages, and, in outline, his great work the "Systema Mycologicum," the first volume of which appeared in 1821 and the last in 1829. In 1825 he sent forth the "Systema Orbis Vegetabilis," first part, a work not further completed, and in 1828 the "Elenchus Fungorum," a commentary on the Systema. In 1831 was published "Lichenographia Europæa Reformata," and in 1838 his second great work, the "Epricisis Systematis Mycologici." About this time he completed the manuscript of a "Synopsis Ascomycetum," in which he had included upwards of 600 new species. Owing to his impatience of the critiques of Corda, Kunze, and the German fungologists who had begun to avail themselves of the new aid of the perfected microscope, an assistance which Fries denied himself, he refrained from publishing it, but one may hope this valuable MS. may still exist. In 1834 he was made Professor of Practical Economy at Upsala, from which place he gave out the "Flora Scanica." He was sent to the Rigsdag in 1844 and 1848 as representative of his university, and was made a member of the Swedish Royal Academy in 1847 In 1851 he succeeded to the chair of Botany at Upsal, vacated by Wahlenberg, which he resigned only a few years before his death to his son. In 1846 he published the "Summa Vegetabilium Scandinaviæ," and in 1860, "Sveriges ätliga och giftiga Svampar," with fine coloured plates. A project of the Royal Society of Holm to publish at its expense drawings of all species of Hymenomycetes under Fries's direction, induced him to write a third and fuller description of the Agarics, of which he printed only 100 copies, under the title of "Monographia Hymenomycetum Suecicæ," in 1863. The first fasciculus, however, of the corresponding "Icones," appeared only in 1867; a second volume was commenced towards the end of last year. Fries lived at Upsal all the latter years of his life, in good health, and in constant correspondence with the botanists of this and other countries, taking, so far as his age permitted, all his early interest in his favourite Agarics. Thus he published, in 1874, a second edition of his "Epicrisis," including in it all the later found European species.

He died, after a short illness, on the 8th inst.

THE TELEPHONE, AN INSTRUMENT OF PRECISION

THE applications to which the telephone may in future be put cannot yet be all foreseen. I have to-day had its value shown to me in a remarkable way. 1. I used a thermo-electric intermittent current by drawing a hot end of copper wire along a rasp completing the circuit. A telephone was put into the circuit, in another room, and every time that the wire was drawn along the rasp a hoarse croaking was heard in the telephone. 2. I used a thermopile with a Bunsen burner shining on it from a distance of six feet. The current was rendered intermittent by the file, and the sound was most distinctly heard. A Thomson's reflecting galvanometer was introduced into the circuit which showed that the currents were extremely small. 3. The feeblest attainable currents were now tried. The thermopile was removed, and without any artificial application of heat it was shown by the galvanometer that the natural differences in the temperatures of the different junctions in the circuit were sufficient to generate feeble electric currents only just perceptible with the mirror galvanometer. These were easily detected by aid of the rasp and the telephone. Even when contact was simply made and broken with the hand, a click was heard in the telephone. 4. Lastly, these feeble currents were rendered still more insignificant by passing them through the body of a friend who held one end of the wire in each hand, and still the effects were faintly audible. Here the galvanometer, which was still in circuit, hardly gave any indication.

I have now added the telephone to the list of apparatus in the laboratory, considering it to be perhaps the most delicate test of an electric current which we possess.

In these experiments only one telephone is used, viz., at the receiving end. Employed in this way with a powerful current sent from the other end of the line, we may hope to have messages sent through submarine cables much more rapidly than at present. Probably it will be best to have the intermittent nature of the current maintained by an induction-coil, or by a spring rubbing against a continuously rotating cog-wheel, when the current is allowed to pass only when required by the depression of a key which communicates to the listener at the receiving end the long and short dashes of the Morse alphabet.

I ought to mention that I believe the person who first used a thermo-electric current with a telephone was Prof. Tait. GEORGE FORBES

Andersonian College, Glasgow, February 13

OUR ASTRONOMICAL COLUMN

LOHRMANN'S LUNAR CHARTS.—At last astronomers are put in possession of the charts of the moon's surface, commenced by W. G. Lohrmann, of Dresden, in 1821. They are now completed in twenty-five sections; but previously only one part, containing four topographical sections, had been published. This was issued at Leipsic in 1824; a small general chart was lithographed at Dresden at a later period. It is through the active interference of Prof. Julius Schmidt, the Director of the Observatory at Athens, whose elaborate lunar work is well known, that the complete publication of Lohrmann's charts has been effected. A pretty detailed prospectus has been circulated. The price of the entire work will be 2*l.* 10*s.*

THE PERIODICAL COMET, 1873 II.—The interesting comet of short period discovered by Tempel on July 3, 1873, was, it is understood, taken in hand by one of the able astronomers attached to the Observatory of Vienna, in which case an ephemeris may soon be expected. The last calculation of elements assigned a period of revolution of only 1,850 days, and it is possible that observations in November, 1873, may have indicated a still shorter period, so that the comet may again arrive at perihelion very early in the summer. Four days after the perihelion passage this comet makes a very near approach to the orbit of Mars, but the recent discovery of satellites to this planet detracts from the importance which would otherwise have attached to a study of the comet's motion, in the hope of eventually improving our knowledge of the planet's mass.

MINOR PLANETS.—Of all the members of this group the elements of which have been calculated, No. 153, *Hilda*, discovered by Palisa at Pola on November 2, 1875, makes by far the nearest approach to the orbit of Jupiter, and on this account it is desirable the planet should be kept under observation at successive oppositions. So far, it does not appear to have been recognised during the present one, though an ephemeris extending to February 20, was given in number 84 of the *Berlin Circular*; this will have been owing, no doubt, to its situation in a part of the sky for which we have no charts showing very small stars. According to the estimation made by Palisa on the night of discovery when the planet's distance from the earth was 3·22, and from the sun 4·20, its brightness at present will be equal to that of a star of the thirteenth magnitude. Subjoined is a continuation of the ephemeris deduced from the best orbit yet available, that by Kühnert, which is founded on observations from November 2 to December 30, 1875:—

HILDA: AT GREENWICH MIDNIGHT.

		R.A.				N.P.D.			Dist. from Earth.
		h.	m.	s.		°	′		
February	28	7	57	36	...	78	49·2	...	3·723

Mr. W. Godward, of the *Nautical Almanac* Office, availing himself of the observations of Ceres which have been made at the Royal Observatory, Greenwich, at every opposition between 1857 and 1876, has corrected the elements of this, the first discovered of the small planets, and has succeeded in representing its course during the interval of about twenty years, with a precision which we do not remember to have seen attained in any previous investigation of the like nature. The residual errors in R.A. and declination in no case amount to five seconds of arc. Applying the corrections given by Mr. Godward in the *Monthly Notices* of the Royal Astronomical Society for January last, there result the following doubtless very exact elements of Piazzi's planet for 1878:—

Epoch, 1878, November 16·0 G.M.T.

Inclination	10	37	17·9	
Angle of eccentricity	4	30	57·2	
Mean daily motion	771″·31117			

From the *Berlin Circular* No. 85, it appears that with the exception of the small planet observed by Prof. Peters on February 6, which proves to be *Antigone*, the planets lately observed are new. Their numbers and discoverers, with dates of discovery and magnitudes, are:—

No. 180	...	Perrotin	...	Jan. 29	...	12·0m.
No. 181	...	Cottenot	...	Feb. 2	...	10·0m.
No. 182	...	Palisa	...	Feb. 7	...	10·5m.
No. 183	...	Palisa	...	Feb. 8	...	12·0m.

As we anticipated, No. 180 proves to be distinct from *Urda*, which remains to be recovered.

BIOLOGICAL NOTES

THE ORIGIN OF THE CARBON OF PLANTS.—Mr. J. W. Moll has made in Prof. Sach's laboratory at Würzburg, some researches on this subject during the summer of 1876. A detailed account of these, with the conclusions at which he has arrived, is promised in the *Landwirthschaftliche Jahrbücher von Nathusius und Thiel*, but a brief account will be found in the last number of the *Archives Néerlandaises*, tome xii., 4me livre. A plant with green-coloured cells can, under the influence of light, take the carbon it requires from the atmosphere, releasing in the act of doing so, so much oxygen. This is a fact, too well vouched for by the experiments of Boussingault, Vogel, Rauwenhoff, and Harting, to admit of a doubt, but the quantity of carbon dioxide in our atmosphere is very small, and the quantity of carbon stored up during say a summer's growth in some large forest, is very great. Moreover, the roots of such plants are fixed in a soil which is highly charged with carbonaceous products, so the question quite naturally arises, may not the roots take up some of these atoms of carbon ready to their hand? or may they not at least take up the carbon in the form of carbon dioxide, send this up the green granules in the leaves, and so give them a more abundant supply than they could get from the surrounding air? Besides, is it not a fact that most plants seem to thrive in a fine rich leaf mould, and may not its richness in carbon be partly the cause? One of the first questions Mr. Moll set himself to answer was—Can leaves decompose carbon dioxide which is furnished to the root of the stem from which the leaves spring? Now, starting with assent to Prof. Sach's discovery that the starch of the chlorophyll granule is the first visible product of the fixation of some carbon atoms, there was here a ready method of proving whether this were so or not. In the course of several experiments it was contrived that leaves destitute of these starch granules should be in an atmosphere deprived of carbon dioxide, while at the same time they were well exposed to the influence of light. The roots were fixed in moist soil well supplied with carbon dioxide, and the result was that under these circumstances no starch granules were formed; and in a modification of this experiment, where one portion of a leaf was allowed to be exposed to ordinary air, that portion at once set to forming its starch. Botanists no doubt will welcome the publication of the experiments of which we have now only the brief result; doubtless more research will end in more discoveries in this most interesting field, for how can one account for the fact that some plants do, as we might say, fatten by feeding on carbon atoms, although these very plants cannot take these atoms when in union with oxygen?

FERNS AND MOSSES.—Hofmeister's work on the "Higher Flowering Plants (Cryptogamia)" is truly indispensable to every scientific botanist, and, thanks to Mr. Curry, the English student has it at his command. It commences with an account of a not uncommon little plant called *Anthoceros lævis*, and it finishes with an account of those cryptogams very high in rank and vast in size, known to us as cone-bearers, and of which the churchyard yew or the giant Wellingtonia may serve as types. Of these cryptogams none are better known than the ferns and the mosses, and as the reader of Hofmeister's work, or, as we are but too glad to be able to add, of most of the very recent handbooks of botany, well know, both of these groups have this in common—that they pass, as it were, through two existences, one of which we may call the "fruit-bearing" stage (the sexual stage), and the other the "spore-bearing" stage (the a-sexual stage). The former of these two is the stage so apparent to us all in flowering plants, where, as a product of the fertilisation of the contents of the carpel by the pollen from the stamens, we have the fruit. In the ferns, as a rule, this first stage is one in which the plant, as it were, thinks only of producing its male and female cells, and the growth of the plant is lost in the care which it takes to continue the species. Shake a spore from the frond of some immense tree-fern, let it germinate, and the plant which will grow thereout will be a little green thing not so big as the top of one's thumb; but it will form its "archegonium" and its "antheridium," and the contents of the latter fertilising the contents of the former, the result will be a plant which in time will equal the large tree-fern in size, but which at this, its great vegetative stage, will never produce aught but spores. In the mosses this state of things is different. The moss-stems which we gather as objects of beauty or use, these are the fruit-producing stages; these concern themselves with growth as well as with what is usually antagonistic to growth, reproduction; and in the second stage, which in the ferns is the only one popularly known, we have but a short-lived, small-sized, spore-producing plant, sometimes quite hid away in the lovely foliage of the moss plant, sometimes starting up from it, and then known popularly as its fruit, but really only its spore-producing stage. It is only very recently that Dr. Karl Goebel (*Botanische Zeitung*, October, 1877) has called attention to the development of the prothallium (sexual stage) of a delicate little fern called *Gymnogramme leptophylla*, which is to be found in Jersey, along both shores of the Mediterranean, and probably in all suitable localities in Africa, Asia, Australia, and South America. It and a few other species are annuals, so that at once we see that their a-sexual stage, which is also their vegetative one, is quite limited. Moreover, their little stems are often not more than an inch in height and the texture of the frond is almost pellucid. It thus approaches the mosses in the feebleness of this stage; but the most interesting fact brought to light by Dr. Goebel is that the sexual stage, generally in the ferns so evanescent, is here absolutely somewhat long-lived, and more, that it is even somewhat vegetative, something like that of *Anthoceros lævis*. Such a form, which makes a bridge to thus connect the two groups (ferns and mosses), is of great importance, and Dr. Goebel's memoir, which is illustrated, is not only of great value from the accuracy of its details and from his deductions therefrom, but also as showing how much can be done even with apparently well-known forms.

PROF. GRIMM ON THE FAUNA OF THE CASPIAN.—We notice the appearance of the second part of Prof. O. A. Grimm's (Russian) work on the Aralo-Caspian Expedition. It is devoted exclusively to the Caspian and to its fauna, and contains the description of worms, sponges, and molluscs, discovered during the expedition, together with a general sketch of the vertical and horizontal distribution of Caspian molluscs. Prof. Grimm divides them into three regions, out of which the lowest one (deep sea) corresponds to older forms of fossils, whilst the upper one has its nearest relatives in youngest forms of fossils. In a concluding chapter Prof. Grimm discusses the interesting question as to the influence of conditions of life on morphological structure, and shows by many illustrations the accommodation of forms to varied conditions at different depths. The work is illustrated by many drawings.

TRANSFORMATION OF CARTILAGE INTO BONE.—The last *Bulletin* of the Belgian Academy of Sciences (vol. xliv. No. 11) contains a very valuable paper of Dr. Leboucq, Superintendent of Anatomical Researches at the University of Ghent, on the mode of formation of the bone tissue in the long bones of mammalians, in which the author discusses and resolves by his researches, based on a new principle, the much-debated question whether the embryonal cartilage is substituted by a new tissue, or is directly transformed into a bone. The great difficulty of rendering the minute cartilage cells apparent among other cells, is resolved by the author by his employing soda, and decalcifying the sections with acidulated glycerine; the cells thus preserve their shape, and receive a beautiful colour, as is seen from a chromolithographed plate accompanying the paper. By using this method the author was enabled to prove that the minute cartilage cells take an active part in the formation of bones, quite performing the part of osteoblastes. The researches were carried out in the Ghent Laboratory, under the direction of Prof. van Bambecke, and the paper is accompanied by a very favourable comment thereon by Prof. van Beneden.

OWLS.—M. Alphonse Milne-Edwards has recently read before the Academy of Sciences of Paris two ornithological papers of interest. One on the affinities of the Owl, *Pholidus badius*, demonstrates, from its skeleton, that it belongs, quite contrary to the general opinion of naturalists, to the Bubonidæ, near to *Syrnium* and *Nyctale*, and not to the Strigidæ. In the species the posterior margin of the sternum has two pairs of well-developed notches, and the furcula is not complete at its symphysial extremity. This being the case, the genus *Strix* is now the only member of the family of the Strigidæ, and the pectination of the inner edge of the nail of the third toe found in it is no longer to be taken as of much importance in the group. In the second paper a new genus of Strigine Owls is described, from Madagascar, and named *Heliodilus*.

ALGÆ OF THE WHITE SEA.—At a recent meeting of the St. Petersburg Society of Naturalists, M. Chr. Gobi read an interesting paper on the algæ of the White Sea. The number of species he has discovered reaches seventy, of which ten are green algæ, six *Fucus*, and twenty-nine red algæ. The algæ of the White Sea are a mixture of representatives of the Arctic and of the Atlantic basins, as well as of fresh water and salt water forms, the mixed characters of the flora being especially obvious with respect to the green algæ.

GEOGRAPHICAL NOTES

LAPLAND.—An important exploration of Russian Lapland is being carried out by the Swedish lieutenant Sandeberg. Hitherto only the coast of the region has been known with anything like accuracy, the interior features being set down solely from conjecture. Lieut. Sandeberg commenced his work in 1876, and we learn from the *Geographische Blatter* (Heft 1, 1878) of the Bremen Society, it will be continued till 1880. The country will be carefully explored and accurate observations taken, which will enable Lapland to be at last mapped satisfactorily. Lieut. Sandeberg is accompanied by several zoologists who are investigating minutely both the mainland, island, and sea fauna, and have already made considerable additions to our knowledge in this direction. During the last two summers Sandeberg has found seventy-eight new species of birds in the Kola peninsula, of which one at least is stated to be quite new to science. Large collections in other departments have also been made. Previous to Sandeberg, no educated European has explored Russian Lapland, which is of such great importance to the zoologist, geologist, botanist, and archæologist. Among other finds it may be mentioned that near Golotizk, on the east coast of the White Sea, he found a great ancient manufactory of flint implements of the stone age, of the purest and highest Scandinavian forms, which previously had been seldom found east of the Baltic, and never on the coast of the Arctic Ocean or the White Sea. The collections will be divided between the State Museums of Russia, Sweden, and Norway, all three countries affording facilities for the conduct of the expedition.

CHINA.—In accordance with the terms of the Chefoo Convention, Her Majesty's minister at Peking, about a year ago, sent to Chung-king, in the Chinese province of Szechuen, which lies at the junction of the River Ho-tow with the Yang-tsze Kiang, Mr. E. Colborne Baber, of her Majesty's Consular Service, who was one of the interpreters attached to the Yunnan mission, and who, before proceeding on that bootless errand, was at considerable pains to qualify himself for scientific exploration. Mr. Baber started last July on an expedition in the western districts of the province. But little was heard of Mr. Baber's doings until the end of the year, except from a private letter in which he described himself as floating down the River Min, among low hills covered with fir and insect wax trees, and in sight of (though at a distance of sixty miles on the south-west) the holy mountain of Omi, on the borders of Thibet. On December 27 the *North China Herald*, of Shanghai, published a portion of another letter from Mr. Baber, in which he mentions that, from the point just named, he made north-west and from Ya-chow began to veer south. Passing Ning-yuan-foo he went to Hwa-li-chow; then turned east and crossed the Yang-tsze into Yunnan, not far from Tung-chwan. Thence through the wildest and poorest country imaginable, the great slave-hunting ground from which the Lolos carry off their Chinese bondsmen—a country of shepherds, potatoes, poisonous honey, lonely downs, great snowy mountains, silver mines, and almost incessant rains, Mr. Baber tracked the course of the Upper Yang-tsze to Ping-shan. No European, he says, has ever been in that region before, not even the Jesuit surveyors, and the course of the Yang-tsze, there called the Gold River (Kin-sha Kiang), as laid down on their maps, is a bold assumption and altogether incorrect. Mr. Baber adds that "a line, drawn south-west from a mile or two above Ping-shan, will indicate its general direction, but it winds about among those grand gorges with the most haughty contempt for the Jesuits' maps."

MOUNT TONGARIRO.—The celebrated burning mountain of New Zealand, Tongariro, has at last been explored by an Englishman, Mr. P. F. Connelly. The volcano is regarded as *tapu*, or sacred, by the Maoris, who have hitherto resisted all attempts to explore the mountain on the part of the colonists. The volcano is situated nearly in the centre of North Island, and though only 6,500 feet high, is less accessible than either Mount Edgecumbe or Ruapehu, both of which exceed 10,000 feet in height. Mr. Connelly overcame all resistance, and by the help of some chiefs more friendly than the rest, succeeded in thoroughly exploring the crater, took a number of sketches and photographs of the locality, and determined the positions of the most important peaks.

AFRICAN EXPLORATION.—The King of the Belgians has sent to M. Quatrefages a telegram stating that two other Belgian officers should proceed to Zanzibar within a few days, to supply the places of the unfortunate MM. Crespel and Maes, whose death we announced last week. Telegraphic orders have been sent to the remaining members of the expedition to continue their journey to Tanganyika. The Paris Geographical Society, anxious to acknowledge such a determined policy, have resolved to take steps to accelerate the public subscription instituted on behalf of international African exploration. It has been resolved also to establish a local committee on a very large scale; not less than a hundred persons of distinction will be selected, with power to add to their number.

PARIS GEOGRAPHICAL SOCIETY.—The distribution of prizes will take place not in April, as usual, but at the meeting to inaugurate the Society's hotel, now building. It will be ready in the month of September or October next. The gold medal will be awarded, as already reported, to Mr. Stanley, but another gold medal of the same value will be given to the veteran M. Vivien de Saint Martin, the celebrated geographer, for the many valuable works published by him during the last thirty years, and principally "L'Année Géographique."

AMERICAN GEOGRAPHICAL SOCIETY.—We have received two numbers of the *Bulletin* of this Society, containing the proceedings of the meetings for the first half of 1877. One number is devoted to the admirable summary of geographical work for 1876, which constituted the address of the President, Chief Justice Daly, and to which we alluded at the time. In the other number (No. 4) the principal paper is on the volcanoes of the U.S. Pacific coast, by Mr. S. F. Emmons.

MAPS OF THE SEAT OF WAR.—The Russo-Turkish war has called forth a very large number of maps of the Balkan peninsula. We learn that a Russian gentleman has made a collection of maps of the seat of war, numbering more than 150, and will exhibit the collection at Paris. The largest number of such maps has been published in Germany, and the most detailed maps appear to be those published in Finland.

ARCTIC EXPLORATION.—Mr. James Gordon Bennett has petitioned the U.S. Congress to grant the American register to the steamer *Pandora* for an Arctic expedition under the command of American naval officers.

SOCIAL ELECTRICAL NERVES[1]

THE efficient carrying out in a large city of any extended system of telegraphic communication for police, fire, and social purposes demands an intimate acquaintance with existing systems, so as to insure the establishment of only the most perfect organisation. In an ordinary telegraphic communication between two or more stations a line wire connects the terminal station with the instruments in the circuit, and the distant end of this wire is in connection with the earth, while the other end, after connection through the instrument, passes to one pole of a battery, the other pole of which is also in connection with the earth. Thus the electrical circuit is completed partly by the line wire and partly by the earth wire. Such is an ordinary circuit. At times when telegraphic communication is required only for short distances, as in houses and buildings, a second wire takes the place of the earth circuit. In the auto-kinetic system for the introduction of fire, police, and social telegraphs upon an extended scale an essential feature is the employment of two parallel wires, laid over a city and suburbs, starting from a central station to the various district stations, and from thence ramifying in every direction so as to embrace the most important areas for the purposes required. Each of these two wires has its special duty to perform. One is employed for the purpose of starting the instrument, which may therefore be termed the "starting" wire. The other is used for the transmission of the message, and may be termed the "transmitting" wire. It is by this novel arrangement that the auto-kinetic system enables any number of speaking stations to be placed upon a circuit without possibility of interference. Thus in each district of a city—say Glasgow—the head police and fire station in the central district will be in direct communication with the sub-stations in the northern, western, southern, eastern, and St. Rollox districts, and each of these again will be local centres, and command a host of street, fire, and police "call" stations placed at convenient distances along the thoroughfares in their respective districts.

---

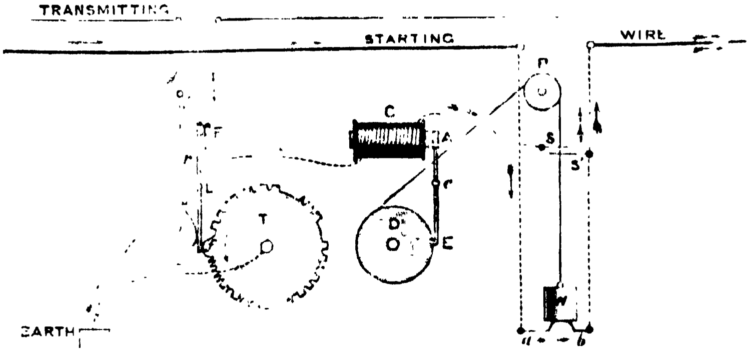
[1] Continued from p. 306.

Another distinctive principle of the auto-kinetic system is that which has already been noticed, namely, the "starting" and "transmitting" wire traversing the streets together. If we suppose a number of speaking stations to be required along the route—say 300—it is evident that at each point where an instrument is placed the two wires will require to be brought into the instrument—the one to start the instrument when a communication is to be sent, and the other to pick up and automatically transmit that message to the district centre. We have before stated that no instrument is "in circuit" except when speaking, and then only during the time occupied in the transmission of the message. It therefore follows that at each station along the line, while in a state of rest, the electrical continuity of both the "starting" and "transmitting" wire must be maintained independent of the apparatus.

A general outline of the manner of employing these two wires will explain the system.

We will commence first with the *modus operandi* of the "starting" wire, then with that of the "transmitting" wire, and finally describe the nature of the automatic apparatus by which the novel and important features of the auto-kinetic system are obtained.

Assume for a moment that the apparatus is inclosed in an iron erection somewhat similar to that of a street pillar letter-box, and that in the inside of this box one portion of the instrument consists of an ordinary electro-magnetic coil C, an armature A, and detent E working on a centre *e* locking into a small arrangement of wheel-work and barrel D, without any maintaining power; and that one end of the wire of this electro-magnetic coil is connected permanently with the earth, the other end being attached to a metallic spring S placed in position to form a contact, under certain conditions, with a second spring S′ in connection with the "lead in" from the starting wire nearest to the district sub-station. In this position as regards the instrument it is a broken circuit, and of course, therefore, the instrument is out of connection. If now we trace the other "lead in" from the "starting" wire and conceive it to be brought into the pillar-post and carried up to the second spring S′, and as from this spring a connection exists with the "starting" wire, a continuous metallic circuit is established through the pillar-box, indicated in the illustration by the ⟷ as far as the passing of "starting" electric currents is concerned from any other instrument along the circuit which may have to travel the wire without affecting the instrument under notice, which remains electrically out of circuit by reason of the break in continuity at the spring S attached to the coil wire. We will now advance a step further, and assume that the continuity of the "lead in" of the "starting" wire furthest from the district station is only maintained so long as a weight W rests upon the two ends *a* and *b*. It will therefore be evident that were the weight W raised, the through continuity at *a b* maintained by the weight would be destroyed, and until so far raised as to mechanically press the springs S and S′ together—the coil wire spring and the lead in "starting" wire spring—the through circuit on the starting wire is broken. Now the weight W being raised what follows? The moment that the springs S and S′ are brought into contact electrical continuity is established between the district station and this instrument, and the battery current flows from that station along the starting wire, passing all intermediate instruments which are necessarily out of circuit, enters the electro-magnetic coil C, and throws the instrument to earth as a terminal with the district centre, at once cutting off all interference that might arise from other instruments along the line speaking at the same time.



Arrangement of Circuits—"Call Station" Instrument.

Thus, for the moment that the two springs S and S′ are in contact, the current has entered the coil C, the armature A has been attracted, and the detent E being withdrawn has liberated the drum D which commences to revolve, having been wound up by the elevation of the weight W.

The liberation of the detent, therefore, instantly causes the weight W to descend, and the act of falling separates the two springs S and S′, the starting wire, as far as this particular instrument is concerned, being thrown off, and the through circuit also remaining broken until the weight has descended and closed the contact by pressure at *ab*.

Before we proceed, let us suppose that during this interval of time between the raising of the weight and its falling, some other instrument or instruments along the line had been called into requisition, what would happen? The weight W at each instrument would have been raised, placing the springs S and S′ in metallic contact, and the instrument thrown into position ready for *speaking*; but as no current could pass along the starting wire until continuity had been restored at the *ab* of the first speaking instrument, which for the moment had become a terminal instrument, no current could enter the coil C of the second instrument; and as the detent E could not be released, the weight would remain suspended, until the arrival of the current along the starting wire attracted the armature and released the drum; in due course the second instrument is immediately thrown off the circuit, and succeeded automatically by a third, fourth, or any number along the line in succession, according to their distance from the district centre or battery station. It will therefore be seen that as the battery current always is in readiness to follow down the "starting" wire from the central station, were twenty or thirty instruments set in action simultaneously; that nearest the central station will record first, and as, in the act of recording, it becomes a terminal, the remainder will follow in the order of their distance along the "starting" wire from the central station. Thus were twenty fires to occur in a district at the same time, and twenty "call" instruments were to be simultaneously put into requisition, the whole twenty would record their several messages without interference at the central station, following one another in successive intervals of time, determined by the automatic falling of the weight on to the circuit poles *a* and *b*. Now, as this interval of time for each instrument is about three seconds, the whole twenty messages would be automatically recorded in about one minute, or less time than it has taken to read the account of what would take place.

We have now traced the action of the "starting" wire, which may be stated to perform its functions mechanically by the act of raising a weight momentarily placing it in circuit with the instrument, which becomes immediately a terminal station; and again by the falling of the weight the instrument is thrown off, and the through circuit along the "starting" wire restored.

We proceed to examine into the action of the second or "transmitting" wire, and explain the process by which, on the starting of the instrument, this picks up automatically the message, and, after transmission, resumes its continuity as a through metallic circuit in relation to the other instruments on the line.

It will be seen, by reference to the diagram, that until the moment that the instrument is thrown on to the circuit of the "starting" wire by the raising of the weight, W, the through continuity of the "transmitting" wire is maintained as indicated by the arrows ⟶, and that the instrument is completely cut out of the circuit. Now the act of starting the drum, D, by the action of the "starting" current, sets in motion, by the force of the descending weight, the small train of wheels before mentioned, the use of which is to give motion to the disc, T, bearing the code message upon its circumference. This disc makes exactly one revolution in the interval of time occupied by the falling of the weight, the distance between the springs, S S′, and the circuit contact, *a b*, upon the restoration of which, the drum, D, is again locked by the detent, E, and the message disc has assumed its normal position.

We will now trace the action of this message disc. The through continuity of the transmitting wire, when the disc is at rest, is maintained by the pressure of the lever, L, upon the two circuit springs, F. This pressure is exerted so long as the disc is in position by means of the insulated stud, *f*, upon which the lower end of the lever, L, rests. The moment, however, that the disc, T, revolves, the lever, L, falls back upon the pin, *r*, the contact between the springs, F, is broken, and the transmitting wire is thrown to earth, through the disc. As the end of the lever, L, comes into metallic contact with the "make" and "break" prominences upon its circumference, currents flow to the central station along the circuit in the direction indicated by the dotted arrows. Now as these currents are passed in groups to represent letters and words, a code message, or any code message out of a given number, may be automatically printed at the receiving instrument at the central station. In the example given, the currents passed are the Morse signals, indicating the position of the calling station, namely, MAIN ST., GORBALS, which would at once inform the central station of the exact locality of the fire. The weight once more at rest, the transmitting wire is no longer to earth at that call station, but is again thrown into circuit by the contact of the springs, F.

From the explanations given, several very important results have been established. Every instrument while transmitting a code message is for the moment made a terminal station, all other instruments on the same circuit being thrown off so as to avoid all possibility of interference. At no time is any greater resistance thrown into the circuit than that of the single instrument employed to transmit the code message. Again, only a very small amount of battery power at the central station is required, only one instrument being in action at the same time. Whatever number of instruments on a circuit may be called into requisition at the same time, they will all automatically record their messages one after the other in succession, commencing with that nearest to the battery station, and be all automatically started and brought to rest, without any mechanical complication of parts or delicate electrical adjustments. Such results have never before been obtained and at once place the *auto-kinetic* system in advance of every other.

A general description of the apparatus, as placed in the hands of the public will now be comparatively easy to understand, and the stability and simplicity of its construction at once recognised.

A messenger presenting himself before any one of the street pillar "call stations" will, on opening the iron door, find a dial plate on which some eighteen or twenty printed sentences are enamelled in bold characters; first, the name of the street indicating the position of the "call station," as in the example given—"Main street, Gorbals"—and following in rotation others, such as "warehouse on fire," "dwelling-house on fire," "mill on fire," "theatre on fire," "send more assistance," "fire got under," "police constable needed," &c. Opposite to each message will be found a substantial knob or handle, something like the "draw-stop" of an organ. The pulling out of the handle opposite the particular code message required causes the instrument to transmit that message to the central station, where it is printed upon a self-recording Morse receiver; and intimation is given to the inspector on duty of the arrival of a "call" by the ringing of a bell during the time the message is being printed. The description previously given of the interior construction of the instrument will readily explain that the pulling out of the handle simply raises the weight, and that the final transmission of the message is indicated by the return of the handle to its normal position upon the descent of the weight. As any number of code message discs may be mounted upon the same shaft, and as each disc would have its special make and break lever acting upon the circuit springs, F, there is little additional complication in the internal arrangement from a plurality of code signals being introduced, the working parts being mostly common to either one or twenty discs. The advantages above described are not the only features of importance in connection with the auto-kinetic system.

A corporation carrying out such a system as described for street police, and fire "call stations," may derive a considerable annual revenue from introducing special "private fire call" instruments into all the large mills, warehouses, works, and more important private dwellings at a small annual charge to the respective owners. As the number of such "private call" stations introduced upon the circuit is practically without limit, irrespective of the money return to a corporation in a commercial view, the great security to property against any very serious loss by fire is a matter of vast importance. It is well known that the annual losses by fire amount to enormous sums, and often thousands of pounds may be lost by a few minutes' delay in giving early intimation of the outbreak to the brigade.

The auto-kinetic system of using the two wires whereby only one speaking instrument can be in circuit at a time, renders them likewise peculiarly adapted for the employment of the telephone in introducing a social system of communication between offices and works, or for the legal profession between the courts and their various offices, as all messages of the most private nature can be sent without publicity, an advantage possessed by no other system.

It is unnecessary to point out any other of the many practical applications to which this auto-kinetic system may be applied. It is a system that must shortly extend its social metallic nerves to all the large centres of commerce and manufacture in this kingdom, and its various applications will then become more fully developed and known.

THE RAIN-TREE OF MOYOBAMBA

SOME little while since a paragraph went the round of the papers, describing, on the authority of the United States Consul in the province of Loreto, a tree existing in the forests near Moyobamba, in Northern Peru.

According to the *Madras Times* and *Overland Mail* of December 15, 1877, "The tree is stated to absorb and condense the humidity of the atmosphere with astonishing energy, and it is said that the water may frequently be seen to ooze from the trunk, and fall in rain from its branches in such quantity that the ground beneath is converted into a perfect swamp. The tree is said to possess this property in the highest degree during the summer season principally, when the rivers are low and water is scarce, and the Consul therefore suggests that the tree should be planted in the arid regions of Peru, for the benefit of the farmers there."

As always happens in cases of this kind, there have not been wanting those who have taken this singular story quite seriously, and the India Office has applied to the Royal Gardens, Kew, on behalf of the Agri-Horticultural Society of Madras for information about the tree. It may be interesting to some of the readers of NATURE, and it will certainly save future correspondence, if I explain once for all what I have been able to ascertain as to the origin of the fable and the amount of truth which it contains.

Pœppig's "Reise in Chile und Peru" (2 vols., 1835), which contains much useful botanical information, apparently makes no reference to the subject.

I am indebted to Dr. Francis Darwin for pointing out to me a very similar account which appears in the *Botanische Zeitung*, January 21, 1876, pp. 35, 36, in which Prof. Ernst, of the University of Caracas, records his observations upon a tree of *Pithecolobium* (*Calliandra*) *Saman*, Benth.

"In the month of April the young leaves are still delicate and transparent. During the whole day a fine spray of rain is to be noticed under the tree, even in the driest air, so that the strongly-tinted iron-clay soil is distinctly moist. The phenomenon diminishes with the development of the leaves, and ceases when they are fully grown."

I found that the specimens of this tree in the Kew Herbarium brought its range close to Moyobamba, as they included some gathered by the traveller Spruce, near the neighbouring town of Tarapoto. It appeared probable, therefore, that the Tamia-caspi—the name given in one variant of the story—was *Pithecolobium Saman*, though the cause of the rain was more mysterious than ever. Being vouched for by so competent an observer as Prof. Ernst, its occurrence could not well be denied, while on the other hand, the *Pithecolobium* being a well-known cultivated tree in the West Indian Islands, it was quite clear that if the "raining" from its foliage were a normal occurrence, it would long ago have been put on record.

Mr. Spruce has, however, obligingly supplied me from the astonishing stores of information which he possesses with the true history of the whole matter, and he has also been so good as to allow me to communicate to the readers of NATURE the substance of what he has told me.

"The Tamia-caspi, or rain tree of the Eastern Peruvian Andes, is not a myth, but a fact, although not exactly in the way popular rumour has lately presented it. I did not know there was any doubt as to the true origin of the 'rain.' I first witnessed the phenomenon in September, 1855, when residing at Tarapoto (lat. 6½° S., long. 76° 20', W.), a town or large village a few days eastward of Moyobamba, and little more than 1,000 feet above the sea-level. I had gone one morning at daybreak, with two assistants, into the adjacent wooded hills to botanise. . . . . A little after seven o'clock, we came under a lowish spreading tree, from which with a perfectly clear sky overhead a smart rain was falling. A glance upwards showed a multitude of cicadas sucking the juices of the tender young branches and leaves, and squirting forth slender streams of limpid fluid. We had barely time to note this when we were assailed by swarms of large black ants, which bit and stung fiercely, and obliged us to beat a retreat, my companions calling out as they ran 'Tamia-Caspi! Tamia-Caspi!' When we had shaken off our assailants, I ventured to approach the spot so near as to make out that the ants were greedily licking up the fluid as it fell. . . .

"My two Peruvians were already familiar with the phenomenon, and they knew very well that almost any tree, when in a state to afford food to the nearly omnivorous cicada, might become (*pro tem.*) a Tamia-caspi, or rain-tree. This particular tree was evidently, from its foliage, an *Acacia*, but as I never saw it in flower or fruit, I cannot say of what species. I came on cicadas, similarly occupied, a few times afterwards, and on trees of very different kinds, but never without the pugnacious ants on the ground beneath. Among the trees on which I have seen cicadas feed, is one closely allied to the acacias, the beautiful *Pithecolobium Saman*. The young branches are very succulent, and they bear elegant bipinnate leaves. . . . The pods are greedily eaten by deer and cattle. Another leguminous tree visited by cicadas is *Andira inermis*, and there are many more of the same and other families which I cannot specify. Perhaps they avoid only such as have poisonous or strongly resinous juices; and those which are permanently tenanted by ferocious ants such as all *Polygoneæ*, the leguminous *Platymiscium*, and a few others. . . . These ants rarely leave the tree which affords them food and shelter, and they jealously repel all intruders, the slightest scratch on the smooth bark sufficing to call their sentinels to the spot. They are quite distinct from the robust marauding ants that drink the cicadas' ejectamenta.

"I have no doubt you have above the true explanation of the Tamia-caspi, or rain-tree. As to the drip from a tree causing a little bog to form underneath and around it, that is a very common circumstance in various parts of the Amazon Valley, in flats and hollows, wherever there is a thin covering of humus, or a non-absorbent sub-soil, and the crown of foliage is so dense as to greatly impede evaporation beneath it. On such sites the Achuál palm (*Mauritia flexuosa*) common enough between Moyobamba and Tarapoto, as well as on the savannahs of the Orinoco, and in subriparial forests of the Amazons—affords a striking example of this property, as has already been remarked by Gumilla, Velasco, Humboldt, and others. Finally, although I never heard the name Tamia-Caspi applied to any particular kind of tree, during a residence of two years in the region where it is now said to be a speciality, it is quite possible that in the space of twenty-one years that have elapsed since I left Eastern Peru, that name may have been given to some tree with a greater drip than ordinary; but I expect the cicada will still be found responsible for 'the moisture pouring from the leaves and branches in an abundant shower'—the same as it was in my time."

Mr. Spruce's notes are so precise and careful that there is little difficulty in accepting his explanation of the rain-tree. It is, however, hard to understand the omission of all insect agency in the equally careful account given by

Prof. Ernst, who attributes the "rain" to secretion from glands on the footstalk of the leaf on which drops of liquid are found, which are rapidly renewed on being removed with blotting paper. It is curious that precisely the same question has been the subject of controversy in the Old World with respect to honey-dew. It is generally believed that this is the result of the aggregate ejecta of Aphides feeding on the juices of the lime. So competent an observer, however, as Boussingault was of opinion that honey-dew was a spontaneous exudation, and it seems not impossible that the lime, as well as the *Pithecolobium Saman* may, under some abnormal circumstances, exude a sugary secretion which insects would eagerly feed on.[1]

W. T. THISELTON DYER

NOTES

WE have to record still another great loss to science in the death on Tuesday, at Rome, of Father Secchi, the eminent astronomer, whose serious illness we recently recorded. We can do no more at present but announce the sad event.

ABOUT 355*l.* have been subscribed to the Darwin Memorial Fund, the idea of which, our readers may remember, originated at Cambridge on the occasion of conferring the degree of LL.D. on Mr. Darwin. We would again draw the attention of our readers to the fund; many of them, we are sure, will be glad to contribute to it, and those who desire to do so should lose no time in sending their subscriptions to the treasurer and secretary, Mr. A. G. Dew-Smith, Trinity College, Cambridge.

A COMMITTEE of members of the several classes of the French Institute, together with a number of eminent scientific men, has been formed to promote the erection of a monument to Leverrier in the grounds of the Paris Observatory. It is expected that foreigners as well as Frenchmen will subscribe.

PROF. FLOWER'S Hunterian Lectures at the Royal College of Surgeons this year will treat of the Comparative Anatomy of Man, more particularly of the Osteological and other Physical Peculiarities of the Races of Australia and the Pacific Ocean. The first two lectures will be devoted to an exposition of the principal methods of craniological research, exemplified by a series of fifty Australian and as many European skulls. The account of the structure of each race will be preceded by a notice of the principal facts of its history and social condition. The lectures commence on Monday next at 4 o'clock, and will be continued at the same hour on Mondays, Wednesdays, and Fridays, till March 28. Any one interested in the subject is admitted.

THE Philosophic Faculty of the University of Zurich has just conferred the degree of Doctor Philos. *honoris causa* on Mr. J. J. Wild, formerly of the scientific staff of H.M.S. *Challenger*, and author of the recent work, "Thalassa," embodying some of the results of that expedition.

THE Photographic Society have awarded to Capt. Abney a silver Progress Medal for having made the greatest advance in the science of photography during the past year.

THE third general meeting of Polish naturalists and physicians will take place at Cracow this year. The two former meetings were held at Posen and Lemberg respectively.

THE Committee of the French Association for the Advancement of Science held a meeting last Thursday. The 16th of August was appointed for the opening of the session, which will be presided over by M. Fremy. The general and sectional meetings will take place at the Hôtel des Beaux Arts, Paris, which contains an immense number of rooms tastefully decorated with fine pictures. The Committee has distributed 8,850 francs among a number of inventors who are constructing machines or scientific apparatus for exhibition. A number of other *encouragements* for similar purposes will be distributed; among the scientific men who will be assisted we are in a position to mention the name of M. Mouchot, for establishing on a large scale his celebrated solar steam-engine.

THE annual session of the Deutsche anthropologische Gesellschaft for 1878 begins at Hamburg on August 11. The meetings on the 12th, 13th and 14th take place at Kiel, and those on the 15th and 16th at Lübeck.

IN the January session of the Berlin anthropologische Gesellschaft, Prof. G. Fritsch delivered an exhaustive address on the subject of Bushman drawings, in which he compared his own observations in the Cape Colony with the late discoveries of Rev. C. G. Büttner in the neighbourhood of Ameib, in the Damara region. These combined results show the widely extended presence of these drawings in South Africa and the existence of a surprising familiarity with perspective and the principles of grouping. In view of the fact that the Bushmen are probably the most degraded race of mankind now existing, dwelling as they do in caves and living from hand to mouth, these evidences of the first principles of art among them possess no small degree of value as explanatory of numerous attempts at illustration before the stone and bronze ages. This is especially the case with the cave dwellers of the so-called reindeer epoch, whose remains have been uncovered recently in France and Switzerland. Anthropologists have had frequent discussions during the past year with regard to the origin of the sketches of animals in the cave of Thainingen, supposed to date back to this epoch; and the opinion has been stoutly maintained that the human race at this stage of development was utterly unable to produce works of this kind. This view will scarcely be tenable in light of these late discoveries among the Bushmen, who are certainly not advanced beyond the stone-age.

IT is expected that the British Archæological Association will hold its annual congress next summer at Wisbeach, to which it has been courteously invited by the Mayor and Corporation. If this arrangement should be definitely made the Prince of Wales will be asked to allow his name to be used as the patron of the congress.

THE Russian division in the Paris Exposition will contain a most interesting anthropological collection, the material for which is now being gathered by a Commission in Moscow. Among the more prominent features are an enormous cranial collection from the various parts of the empire, and a model of a Russian barrow. The latter is being executed by the sculptor, Ssewojugin, in natural size, and will offer a perfect imitation of the skeletons, ornaments, weapons, &c., as usually found in these ancient remains. The Russian educational system will be likewise very fully represented, as was the case in 1876.

THE official report of the Munich Session of the German Scientific Association, which took place last September, has just appeared. It forms a volume of 264 quarto pages, and has been prepared with unusual care. Reports of all addresses delivered have been furnished by the speakers themselves, who numbered considerably over a hundred. The number of members and participants in the last session was 1,800, of whom 650 were from Munich or its vicinity. We notice that the Society is exceedingly strict in the observance of one of its statutes stating that it shall possess no property with the exception of its archives, for the receipts exactly cover the expenses.

THE death is announced of Major-General Sir Andrew Scott Waugh, F.R.S., of the Royal Engineers, at the age of sixty-eight. He entered the Bengal Engineers in 1827, and assisted in the making of the great Trigonometrical Survey of India in 1832. He also took a leading part under Sir George Everest in the measurement of the great Indian arc for determining the figure and dimensions of the earth. In 1843 he was appointed Surveyor-General of India and Superintendent of the Trigonometrical Survey. He received the honour of knighthood in 1860, and the Gold Medal of the Royal Geographical Society in 1857-58.

---

[1] I have translated Boussingault's paper, and collected the evidence on both sides, in the *Journal* of the Royal Horticultural Society, new series, vol. iv. pp. 1-7.

MM. Henry brothers, the celebrated astronomers, have invented a telegraphic warning apparatus, which can be used for telephones. It is powerful, cheap, and simple, and musical sounds emitted can be heard at a distance without placing the ear at the opening of the mouth-piece.

The *Gardener's Chronicle* announces that M. Thuret's fine garden at Antibes has fortunately become the property of the French nation, and will be constituted a Mediterranean branch, as it were, of the Jardin des Plantes at Paris. The direction will be in the hands of M. Naudin, now of Collioure, who in this new field of action will have greater scope than before for his experiments in naturalisation. The object is to maintain the garden as a botanic and experimental garden, where all new introductions may be tried and distributed to other gardens.

It is stated that the German poet, Friedrich Bodenstedt, the author of the charming "Lieder des Mirza Schaffy," is now engaged in translating the poems of the Persian philosoper Omer Cheijan. The latter was born at Nishaboor, in the twelfth century, and was one of the greatest astronomers and philosophers of his time. He recorded the results of his studies in verse.

At a village near the well-known German watering place, Langenschwalbach (in the Prussian province of Nassau) some interesting experiments have been recently made with the common nettle (*Urtica dioica*). They consisted in working this weed in the same manner as hemp; the fibres obtained were fine as silk, while they yielded nothing to hemp fibres as regards durability. A considerable area has now been planted with nettles at the locality named.

Some highly interesting antiquities were recently found near Wisby, on the Swedish island of Gottland, in the Baltic. Excavations are being made for a new railway, and in a gravel pit, about a foot under the surface, a copper casket was found, which contained two sets of bronze weights, each set consisting of five different pieces, and belonging to an old Arabic monetary system. Besides these weights there was a peculiar magnifying glass in the box, while on the top of all there were found two balance scales, a larger and a smaller balance beam, the former with chains, the latter with flaxen strings, which were still preserved. All the objects were artistically finished and made of bronze.

Prof. Leidy has been engaged, in connection with Dr. Hayden's expedition during the past season, in exploring the region about Fort Bridger, Uintah Mountains, and the Salt Lake Basin, with special reference to the occurrence there of rhizopods. These have been for several years the special object of Prof. Leidy's attention, and his extensive manuscripts, with many coloured drawings, will probably be published before long.

Mr. W. H. Holmes, the artist of Dr. Hayden's party, has been prosecuting explorations among the Pueblo villages, both ancient and modern, in Northern New Mexico and Arizona, and has collected data for making models in plaster of the pueblos of Taos and Acorna, which will probably be added to the superb series of these archæological restorations deposited by Prof. Hayden in the National Museum.

We understand that the National Entomological Exhibition, which will be opened at the Royal Aquarium, Westminster, on March 9 is likely to be a great success. Already several thousand square feet of space have been applied for.

It is surprising to hear that M. Kuhmkorf's workshop has been sold by auction at the ridiculous price of 42*l*.

A novel use of the telegraph has lately been adopted by the Norwegian Government. As is well known, the herring fishery forms one of the most important sources of income for the country, the captures being made as the great shoals come from the depths of the sea to deposit their spawn in the Norwegian fiords. It frequently happens that the object of their visit is accomplished, and they return to the ocean before news of their arrival reaches the fishers on distant parts of the coast. This difficulty is now obviated by the construction of a telegraphic line, 200 kilometres in length, composed chiefly of submarine cables, by means of which the fishers along the whole coast are enabled to gather at once on the approach of a shoal to any particular fiord. The abundant captures made in this way show the investment in telegraphic wire to have been a most profitable speculation.

Baron von Bibra states in the *Journal für praktische Chemie*, that he has been enabled to restore the handwriting in old manuscripts, by washing them with a solution of tannin, and drying at 75° C. He has likewise found that nitro-benzene can be used for the restoration of antique paintings, whether painted on wood or canvas.

A strange little work has just been published at Weimar (Weissbach); its title is "Das Buch der Katzen," its author Herr Gustav Michel. In six letters the author gives an interesting account of the somewhat rich material, treating the same in turn from a scientific, historic, domestic, religious, and mythological point of view.

In a communication to the American Philosophical Society on the 1st inst., by Mr. A. Wilcocks, of Louisiana, the author describes an interesting observation which he made of a shadow cast by Venus, against a white wall, in a piazza. "The shadow of a hand," he states, "distant twelve feet from the wall, I found perfectly sharp and well defined. And more striking still, the shadow of the twigs of a pecan tree, distant fifty yards, were also sharp. These last shadows were faint, from the effect of the diffused light of the sky which illumined the wall."

We take the following interesting statistical data from the *Jahresbericht* for 1877 on the establishments of the world-known firm of Krupp at Essen, Rhenish Prussia. The number of workmen in the cast-steel works amounts to 8,500. There are 298 steam-engines with separate boilers in the establishment, and the total of their horse-power amounts to 11,000. Besides these there are 77 steam hammers at work varying in weight from 2 cwt. to 50 tons. The products in every 24 hours amount to about 12 English miles of rails with tyres, axles, wheels, springs in proportion, as well as 1,500 shells of various sizes and constructions. In one month 300 guns (of various bores) are produced. Since 1847 no less than 15,000 cannon have been made. The daily consumption of coal and coke is 1,800 tons. There are 21,000 gas flames on the works. A railway of 60 kilometres length, with [24 locomotive engines, and 700 carriages exclusively belongs to the establishment; there are also 44 different telegraph stations, and a fire brigade with 8 engines. A new shooting ground of 18 kilometres length is now being adapted near Meppen (Hanover). In the coal and other mines belonging to the firm there are 5,300 workmen. Their mines in northern Spain produce 200,000 tons of iron ore annually; 5 steamers belonging to the firm convey these ores to their destination. The metallurgical establishment contains 700 workmen. In 3,277 workmen's dwelling-houses built by the firm there live 16,200 men, women, and children. They are supplied with provisions, &c., at 22 stores at wholesale prices. The bakehouse produces about 195 tons of bread per day. Last, but not least, there are 4 general schools with 21 classes, and an industrial school for girls and women on the establishment, LORD JOHN MANNERS stated in the House of Commons on Thursday last that experiments have been made by officers of the Post-Office with the telephone, the result being that the instrument is not at present considered suitable for public telegraphy.

IN Prof. Lebour's letter on Marine Fossils in the Gannister Beds of Northumberland, in last week's NATURE, the word *country* should have been *county*. It is the first time marine forms have been found in this series in Northumberland.

THE additions to the Zoological Society's Gardens during the past week include two Black-winged Pea-Fowls (*Pavo nigripennis*) from Cochin China, presented by the Hon. A. S. G. Canning, F.Z.S.; a Javan Parrakeet (*Palæornis javanica*) from Muttra, North-West India, presented by Mr. Barthorp; two Red-vented Bulbuls (*Pycnonotus hæmorrhous*) from India, presented by Col. A. L. Annerley, F.Z.S.; two Leopards (*Felis pardus*) from Persia, deposited; two Barbary Wild Sheep (*Ovis tragelaphus*) from North Africa; two Pale-headed Parrakeets (*Platycercus pallidiceps*) from North-East Australia; four Turquoisine Parrakeets (*Euphema pulchella*) from New South Wales, purchased; two Tigers (*Felis tigris*), born in the Gardens.

ON COMPASS ADJUSTMENT IN IRON SHIPS[1]

II.

AN important objection was made to me some years ago by Capt. Evans against the use of quadrantal correctors in the Navy, that they would prevent the taking of bearings by the prismatic azimuth arrangement, which forms part of the Admiralty standard compass. The azimuth mirror (Fig. 5) applied to the compass before you was designed to obviate that objection. Its use even for taking bearings of objects on the horizon is not interfered with by the globes constituting the quadrantal correctors, even if their highest points rise as high as five inches above the glass of the compass-bowl. It is founded on the principal of the camera lucida. The observer when taking a bearing turns the instrument round its vertical axis until the mirror and lens are fairly opposite to the object. He then looks through the lens at the degree divisions of the compass-card, and turns the mirror round its horizontal axis till he brings the image of the object to fall on the card. He then reads directly on the card the compass bearing of the object. Besides fulfilling the purpose for which it was originally designed, to allow bearings to be taken without impediment from the quadrantal correctors, the azimuth mirror has a great advantage in not requiring any adjustment of the instrument, such as that by which, in the prism compass the hair is brought to exactly cover the object. The focal length of the lens in the azimuth mirror is about 12 per cent. longer than the radius of the circle of the compass-card, and thus, by an elementary optical principle, it follows that two objects a degree asunder on the horizon will, by their images seen in the azimuth mirror, cover a space of 1°·12 of the divided circle of the compass-card seen through the lens. Hence, turning the azimuth instrument round its vertical axis through one degree will only alter the apparent bearing of an object on the horizon by ·12°. Thus it is not necessary to adjust it exactly to the direct position for the bearing of any particular object. If it be designedly put even as much as 4° awry on either side of the direct position, the error on the bearing would hardly amount to half a degree. If the instrument were to be used solely for taking bearings of objects on the horizon, the focal length of the lens should be made exactly equal to the radius of the circle, and thus even the small error of ·12° in the bearing for one degree of error in the setting would be avoided. But one of the most important uses of the azimuth instrument at sea is to correct the compass by bearings of sun or stars at altitudes of from 0° to 50° or 60° above the horizon. The actual focal length is chosen to suit an altitude of 27°, or thereabouts (this being the angle whose natural secant is 1·12). Thus if two objects whose altitudes are 27°, or thereabouts, and difference of azimuths 1°, are taken simultaneously in the azimuth mirror, their difference of bearings will be shown as one degree by the divided circle of the compass-card seen through the lens. Hence for taking the azimuth of star or sun at an altitude of 27°, or thereabouts, no setting of the azimuth mirror by turning round the vertical axis is necessary, except just to bring the object into the field of view, when its bearing will immediately be seen accurately shown on the divided circle of the compass-card. This is a very valuable quality for use in rough weather at sea, or when there are flying clouds which just allow a glimpse of the object, whether sun or star, to be caught, without allowing time to perform an adjustment, such as that of bringing the hair, or rather the estimated middle of the space traversed by the hair in the rolling of the ship, to coincide with the object. The same degree of error as on the horizon, but in the opposite direction, is produced by imperfect setting round the vertical axis in taking the bearing of an object at an elevation of 38°.

Thus for objects from the horizon up to 38° of altitude the error in the bearing is less than 12 per cent. of the error of the setting. For objects at a higher elevation than 38° the error rapidly increases; but even at 60° altitude the error on the bearing is a little less than half the error of the setting; and it is always easy, if desired, to make the error of the setting less than a degree by turning the instrument so that the red point, which you see below the lens, shall point within a degree of the position marked on the circle of the compass-card by the image of the object.

For taking star azimuths the azimuth mirror has the great advantage over the prism compass, with its then invisible hair, that the image of the object is thrown directly on the illuminated scale of the compass-card. The degree of illumination may be made less or more, according to faintness or brilliance of the object, by holding a binnacle lamp in the hand at a greater or less distance, and letting its light shine on the portion of the compass-card circle seen through the lens. Indeed, with the azimuth mirror it is easier to take the bearing of a moderately bright star by night than of the sun by day: the star is seen as a fine point on the degree division, or between two, and it is easy to read of its position instantly by estimation to the tenth of a degree. The easiest, as well as the most accurate of all, however, is the sun when bright enough and high enough above the horizon to give a good shadow on the compass-card. For this purpose is the stout silk thread which you see, attached to the framework of the azimuth mirror in such a position that when the instrument is properly placed on the glass of the compass-bowl, the thread is perpendicular to the glass and through the central bearing-point of the compass.

Another advantage of the azimuth mirror particularly important for taking bearings at sea when there is much motion, is at with it it is not necessary to look through a small aperture an instrument moving with the compass-bowl, as in the dinary prism compass, or in the original nautical azimuth ompass (described 280 years ago by Gilbert, Physician in rdinary to Queen Elizabeth, in his great Latin book. "On the agnet and on the Earth a great Magnet"), which is very much e same as that still in use in many of the best merchant steamers. using the azimuth mirror the eye may be placed at any istance, of from an inch or two to two or three feet, from the ompass, according to convenience, and in any position, and may e moved about freely through a considerable range on either side f the line of direct vision through the lens, without at all isturbing the accuracy of the observation. This last condition secured by the lens being fixed in such a position of the nstrument that the divided circle of the compass-card is in its rincipal focus. Thus the virtual image of the divided circle is t an infinite distance, and the images of distant objects seen coincidently with it by reflection in the plane mirror show no shifting n it, that is to say, no parallax, when the eye is moved from the entral line to either side. From the geometrical and optical rinciples explained previously, it follows also that if the zimuth instrument be used for taking the bearing of an object hose altitude is less than 27°, then the effect of turning the frame arrying the lens and mirror in either direction will seem to arry the object in the same direction relatively to the degrees of he card; or in the contrary direction if the altitude exceeds 7°. But if the altitude of the object be just 27°, then the zimuth instrument may be turned through many degrees on ither side of the compass-card, without sensibly altering the pparent positions of the objects on the degree-divisions.

---

[1] Report of paper read to the Royal United Service Institution, February 4, by Sir Wm. Thomson, LL.D., F.R.S., P.R.S.E., Professor of Natural Philosophy in the University of Glasgow, and Fellow of St. Peter's College, Cambridge. Revised by the Author. [The Council of the R.U.S.I. have kindly permitted us to publish Sir W. Thomson's paper in advance, and have granted us the use of the illustrations.—ED.] Continued from p. 334.

I.—*An Adjustable Deflector for completely determining the Compass Error when Sights of Heavenly Bodies or Compass Marks on Shore are not available.*

About thirty years ago Sir Edward Sabine gave a method n which, by aid of deflecting magnets properly placed on projecting arms attached to the prism circle of the Admiralty tandard compass, a partial determination of the error of he compass could be performed at any time, whether at sea r in harbour, without the aid of sights of heavenly bodies or compass marks on shore. The adjustable magnetic deflector before you is designed for carrying out in practice Sabine's method more rapidly and more accurately, and for extending it, by aid of Archibald Smith's theory, to the complete determination of the compass error, with the exception of the constant term "A" of the Admiralty notation, which in almost every practical case is zero, and can only have a sensible value in virtue of some very marked want of symmetry of the iron work in the neighbourhood of the compass.[1] When it exists it can easily be determined once for all and allowed for as if it were an index error of the compass card, and it will, therefore, to avoid circumlocutions in the statements which follow, be either supposed to be zero or allowed for as index error.

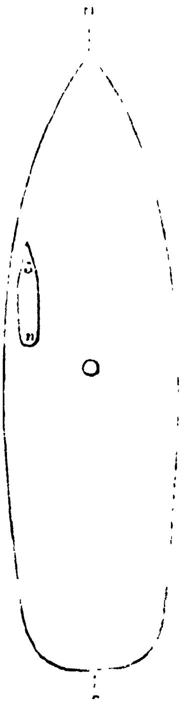


FIG. 6.

The new method is founded on the following four principles:—

1. If the directive force on the compass needles be constant on all courses of the ship, the compass is correct on all courses.

2. If the directive force be equal on five different courses, it will be equal on all courses.

3. Supposing the compass to be so nearly correct or to have been so far approximately adjusted, that there is not more than eight or ten degrees of error on any course, let the directive forces be measured on two opposite courses. If these forces are equal the compass is free from semicircular error on the two courses at right angles to those on which the forces were measured; if they are unequal there is a semicircular error on the courses at right angles to those on which the forces were measured, amounting to the same fraction of the radian (57·3°) that the difference of the measured forces is of their sum.

4. The difference of the sums of the directive forces on opposite courses in two lines at right angles to one another, divided by the sum of the four forces, is equal to the proportion which the quadrantal error, on the courses 45° from those on which the observations were made, bears to 57·3°.

The deflector may be used either under way or in swinging the ship at buoys. The whole process of correcting the compass by it is performed with the greatest ease and rapidity when under way with sea room enough to steer steadily on each course for a few minutes, and to turn rapidly from one course to another. For each operation the ship must be kept on one course for three or four minutes, if under way, by steering by aid of an auxiliary compass, otherwise by hawsers in the usual manner if swinging at buoys, or by means of steam-tugs. A variation of two or three degrees in the course during the operation will not make a third of a degree of error in the result as regards the final correction of the compass. The deflector reading is to be taken according to the detailed directions in sections 14 and 15 of the printed "Instructions." This reading may be taken direct on the small straight scale in the lower part of the instrument. The divided micrometer circle at the top is scarcely needed, as it is easy to estimate the direct reading on the straight scale to a tenth of a division, which is far more than accurate enough for all practical purposes. This reading with a proper constant added gives, in each case, the number measuring in arbitrary units the magnitude of the direct force on the compass for the particular course of the ship on which the observation is made.

The adjustment by aid of the deflector is quite as accurate as it can be by aid of compass marks or sights of sun or stars, though on a clear day at any time when the sun's altitude is less than 40°, or on any clear night, the adjuster will of course take advantage of sights of sun or stars, whether he helps himself also with the deflector or not.

III.—*New Form of Marine Dipping Needle for facilitating the Correction of the Heeling Error.*

This instrument is designed as a substitute for the vibrating vertical needle, hitherto in use for carrying out the observations of vertical force, whether on board ship or on shore, required for performing the operations described in Part iii. Section 4, and ths last three pages of Part iv. of the Admiralty Manual. It consists of a light bar-magnet or "needle" of hardened steel wire, supported by means of a very small aluminium cradle on a stretched platinum wire, of which the two straight parts on the two sides of the needle are, as nearly as may be, in a line through its centre of gravity. One flat end of the needle is painted white, with a black line through its middle parallel to the platinum wire. When the instrument is properly placed for use the platinum wire is horizontal, and the needle is brought into a horizontal position by turning one end of the platinum wire until the elastic force of the torsion balances the turning motive (or "couple") due to the vertical component of the magnetic force of the locality. A divided circle is used (as the torsion head of the original Coulomb's Torsion Balance) to measure the degrees of torsion to which, according to Coulomb's original discovery, the turning motive is proportional. Thus, the magnetic moment of the needle being constant, the vertical component of the magnetic force in the locality of the observation is measured simply in degrees or divisions of the torsion head. A glass plate, fixed in a vertical position parallel to the platinum wire and close to the painted end of the needle, has a horizontal score across it on the level of the platinum wire. By aid of a totally reflecting prism, like that of the prismatic azimuth compass, with one side convex, the user of the instrument looking downwards sees when the black line on the end of the needle is exactly level with the score on the glass plate. This mode of sighting has proved very satisfactory; it is very easily and quickly used, and it is so sensitive that with the dimensions and magnetic power of the instrument before you it shows easily a variation of vertical force amounting to $\frac{1}{100}$ of the earth's vertical force in this locality. The accompanying printed instructions for the adjustment of my compass describe in sufficient detail the way of using it for correcting the heeling error.

---

[1] I had a curious case lately of the effect of unsymmetrical iron on a midship steering compass, due to a steam-launch about thirty feet long placed fore-and aft on the port side of the deck with its bow forward and its stern five or six feet before the thwart-ship line through the position of the compass. Adjustment having been performed by means of the globes and magnetic correctors to correct the quadrantal error (D), and the semicircular error, it was found (as was expected) that the compass was correct on the east and west points, but showed equal westerly errors of about 3½° on the north and south points. There were, therefore, approximately equal negative values of "A" and "E" each 1¾°. The captain was, of course, warned of the change he would find when he was relieved of the steam-launch at Rangoon, the port of his destination. The explanation of the westerly deviation when the ship's head was north or south, by the inductive magnetism of the steam-launch, according to which its stern would be a true north pole when the ship is on the north course, and a true south pole when the ship is on the south course, is obvious from the annexed diagram, in which the letters n, s, denote true north pole and true south pole of induced magnetism in he steam-launch when the ship's head is north magnetic.

In the instrument before you there is a divided paper circle in the bottom of the box to serve as a "dumb card," to be used with the azimuth mirror when there may be occasion for the use of a non-magnetic azimuth instrument. This appliance has nothing to do with the dipping needle, and is introduced because, while adding little or nothing to the cumbrousness of the instrument, it saves the adjuster the necessity for carrying a separate azimuth instrument with him.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—From the University Calendar for 1878 we learn that the Undergraduates, who were last year 2,590, have now risen to 2,659, while the members of Convocation have increased from 4,870 to 5,026. During the year 320 have taken the degree of Master of Arts, and 446 that of Bachelor of Arts. The number of matriculations, which in 1868 was 579, and which in 1876 was 650, rose in 1877 to 770. But this increase was due to the number of candidates for a musical degree. The list of members of Congregation—that is, of the legislative body of resident members of Convocation—has increased, but only slightly. In 1876 they numbered 314; in 1877, 322. But the proportion between clergymen and laymen has considerably changed during the year. In 1876 there were 180 clergymen and 134 laymen; in 1877 the laymen have risen to 154, and the clergymen have fallen to 168. Of the whole body of Fellows (exclusive of Christ Church), resident and non-resident, there are at present 102 laymen and 116 clergymen.

CAMBRIDGE.—The Council of the Senate having had under consideration a letter from Prof. Hughes, Woodwardian Professor of Geology, representing the need for additional assistance, propose that an assistant be appointed, with a stipend of 200*l.* per annum, whose duties shall be to assist the Professor in the arrangement and care of the geological collections, to give such instruction and demonstrations as may be required, and to assist students making use of the museum. It is proposed to vest the appointment in the Professor, with the consent of the Vice-Chancellor.

EDINBURGH.—A site has been secured in Chambers Street, close by the University, for the erection of a new school of medicine for extra-academical teachers, on the spot formerly occupied by Minto House, so long the scene of the demonstrations and prelections of eminent extra-mural lecturers.

TAUNTON COLLEGE SCHOOL.—A microscopic cabinet by Smith and Beck, with other valuable apparatus, has been presented to the Rev. W. Tuckwell by his late assistant-masters at he Taunton College School, as an expression of their personal ympathy and their recognition of the services rendered by him to he higher education.

PRUSSIA.—January 20 was a red letter day for a number of professors in Prussian universities, no less than fifteen receiving rders of different ranks from the Emperor William.

DRESDEN.—On May 1 the Royal Polytechnic Institution at Dresden will celebrate the fiftieth anniversary of its foundation. Originally confined to the narrowest limits, the Institution has apidly developed, and is now one of the most frequented polytechnic schools of Germany.

GREIFSWALD.—The attendance on the university shows a decrease as compared with the past summer. The students number 43 in the theological faculty, 73 in the legal, 126 in the philosophical, and 218 in the medical. The corps of professors and privat-docenten is at present 60. A library of 60,000 volumes, well equipped laboratories and collections, and ample revenues place Greifswald on a par with most German universities, but for a number of years it has failed singularly to compete in point of attendance with many poorer centres of study.

TÜBINGEN.—The university shows at present the highest winter attendance since its foundation. The students are divided as follows: Theology (evangelical), 215, (catholic), 108; law, 256; natural sciences and medicine, 222; philosophy, 145.

MÜNSTER.—Prof. R. Sturm, of the Darmstadt Polytechnic, has been appointed to the chair of mathematics, rendered vacant by the late death of Prof. Heis. The number of students at present is 312.

BERLIN.—Prof. Schwedener, of Tubingen, has received a call to Berlin to fill the second professorship for Botany lately created at the University.

VIENNA.—In the lately presented educational budget of Austria the sum of 50,000*l.* is appropriated for the erection of new buildings for the Vienna University.

DORPAT.—The hitherto rigorous rule of Russian universities requiring from all instructors the possession of Russian diplomas of the doctorate, &c., has been modified in the case of Dorpat, recognition being made of foreign degrees and professorial positions.

SIBERIA.—The Imperial Commission appointed to settle the long-debated question as to the University of Siberia, has definitively given the preference to Tomsk, against Omsk. We are glad to learn this result, because of the central position of Tomsk, its larger population, not exclusively administrative, as at Omsk, and the larger number of secondary schools. Several Siberian merchants have endowed the future University with considerable sums of money.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 31.—"On the Expression of the Product of any Two Legendre's Coefficients by means of a Series of Legendre's Coefficients," by Prof. J. C. Adams, F.R.S.

Royal Society, February 24.—"On the Use of the Reflection Grating in Eclipse Photography," by J. Norman Lockyer, F.R.S.

The results obtained by the Eclipse Expedition to Siam have led me to think that, possibly, the method of using the coronal atmosphere as a circular slit, suggested by Prof. Young and myself, for the Indian eclipse of 1871, might be applied under very favourable conditions, if the prism or train of prisms hitherto employed were replaced by one of those reflection gratings with which the generosity of Mr. Rutherfurd has endowed so many of our observers.

To test this notion I have made some experiments with a grating, which I owe to Mr. Rutherfurd's kindness, containing 17,280 lines to the inch. The results of these observations I have now the honour of laying before the Royal Society.

In front of the lens of an ordinary electric lamp, which lens was adjusted to throw a parallel beam, I have introduced a circular aperture, cut in cardboard, forming an almost complete ring, some two inches in interior diameter, the breadth of the ring being about $\frac{1}{8}$ inch. This was my artificial eclipse.

At a distance from the lamp of about thirteen yards, I mounted a $3\frac{3}{4}$ inch Cooke telescope, of fifty-four inches focal length. Some distance short of this focus I placed Mr. Rutherfurd's grating, and, where the first order spectrum fell, I placed a focussing screen. To adjust for sharp focus, in the first instance, the grating was so inclined to the axis of the telescope that the image of the ring reflected by the silver surface adjacent to the grating was thrown on to the screen. This done, the grating was placed at right angles to the axis, and the spectrum of the circular slit, illuminated by sodium vapour and carbon vapour, photographed for the first, second, and third orders on one side. The third order spectrum, showing the exquisite rings due to the carbon vapour flutings was produced in forty-two seconds. The first order spectrum, also submitted to the Society, was produced in the same period of time, and was very much over-exposed; it is, therefore, I think not expecting too much that we should be able to take a photograph of the eclipse, in the third order, in two minutes; but let us make it four. Similarly, we may hope for a photograph of the second order in two minutes, and it is, I think, highly probable also that a photograph of the first order may be obtained in one minute.

It is clear then that, by mounting photographic plates on both sides of the axis, one solidly mounted equatorial of short focal length may enable us to obtain a large number, with varying lengths of exposure, of the next eclipse. I have insisted upon the solidity of the mounting because, if any one plate is to be exposed during the whole of totality, the instrument must not be violently disturbed or shaken while the eclipse is going on. I think, however, it is quite possible to obtain many photographs, of the lower order spectra, without any such disturbance. The same plate may be made to record three, or even four, exposures in the case of the first order, by merely raising or lowering it after a given time, so that a fresh portion of the same plate may be exposed, by means of a rapid screw or other equivalent contrivance. Similarly, the plates on which the spectra of the second order are to be recorded may be made to perform double duty.

Linnean Society, February 7.—Prof. Allman, F.R.S., president, in the chair.—Sir John Lubbock, Bart., read a paper, "Observations on the Habits of Ants," being his fifth contribution on this subject. In continuation of former experiments he finds that ants recognise old acquaintances and attack strangers. Their intelligence is questionable in cases where a thin circle of glycerine bars their access to honey which they have already visited by a paper bridge, for when the latter is taken away they do not pile up a few grains of earth and thus cross the barrier. Spite of the many observers and plentifulness of ants' nests, it is still doubtful how their nests commence. Sir John's experiments show that the workers of *Lasias flavus* will not adopt an old queen from another nest. But on the other hand, the queen of *Myrmica ruginodis* has the instinct of bringing up larvæ and the power of founding communities. As to intimating to each other discovery of food, he considers this does not necessarily imply any power of describing localities, but rather by a simple sign co-workers accompany each other to the treasure. They do not summon their brotherhood by sounds to a repast found by one or another. Their affection for friends is outbalanced by hatred of strangers. A few of each kept prisoners in separate bottles with wide meshed muslin over the mouths, those free outside again and again excitedly endeavoured to attack the latter, but used no means to free the former, their own companions. Further experiments prove scent more than sight guides them in following up food which has been shifted in position after its having been partaken of, and a return to the nest made. Ants avoid light when thrown into their nests, and they then congregate into the darkest corners. Taking advantage of this habit by a series of ingenious experiments—wherein strips of coloured glass, in other instances shallow cells containing coloured solutions, such as fuchsine, bichromate of potash, chloride of copper, &c., were used—Sir John arrives at the conclusion that they are influenced by the sensation of colour, though probably different from the effect produced in man. A predominate preference is given to red, green follows, yellow comes next, while to blue and violet there appears to be a decided aversion. The longevity of ants would seem greater than generally admitted, some specimens of *Formica fusca* being at least five years old.—Mr. Thiselton Dyer made a brief communication on the so-called "rain-tree" of Mogobamba, South America, an account of which we give elsewhere. —Then followed a paper "On the shell of the Bryozoa," by Mr. Arthur W. Waters. The points he more particularly drew attention to were:—The great difference of the young and old cells caused by a constant growth of shell-substance, so that the older zooecia become closed up. This growth progresses at various rates. Passing through the shell are tubes filled with corpuscles of the chylaqueous fluid, which thus become oxidised. The supposed nervous filament of the colonial connection the author believes to be rather for the supply of material from one part of the zooarium to another. He further suggests that the varying thickness of the plates in the walls of the colonial connection should be used as a factor in specific determination, and especially would it be useful in comparing recent and fossil forms. There is a possibility of the avicularia and adventitious tubes being homologous, and helping to maintain the vitality of the colony when the polypides have disappeared.—Messrs. A. G. Agar and C. Berjeau were elected Fellows of the Society.—The President having put the motion, it was unanimously resolved to present an address to Prof. C. T. Ernst von Siebold on his approaching jubilee.

Zoological Society, February 5.—Prof. Mivart, F.R.S., vice-president, in the chair.—Prof. Mivart read a paper entitled "Notes on the Fins of Elasmobranchs, with Considerations on the Nature and Homologies of Vertebrate Limbs," wherein the author detailed his dissections of the fins of Elasmobranchs, which dissections had convinced him that the paired and azygos fins are of similar nature. He represented them all to have resulted from the centripetal growth and coalescence of a primitively distinct series of cartilaginous rays developed in longitudinal folds, of which one was dorsal, one ventral, and two were lateral. He also advocated the view that the limb-girdles result from the further centripetal growth of the coalescing limb-cartilages, which growth seeks a *point d'appui*, the pectoral limb-girdles in fishes shooting upwards and downwards, as well as inwards to obtain a firm support, and, at the same time, to avoid the visceral cavity. He contended that the Archipterygium was not to be sought for in *Ceratodus*, which he by no means regarded as a primitive type of structure, but rather in *Raia* and especially in the ventrals of *Polyodon*. He objected to Gegenbauer's view that the metapterygium formed the limb axis of the cheiropterygium, advocating instead the propterygium, or, if not that, then the mesopterygium. He cited the varying conditions described as evidences of the presence of an innate intra-organic polar force as the main agent in morphological modifications.—A communication was read from Mr. W. A. Forbes, F.Z.S., containing an account of the birds collected by the *Challenger* Expedition at Cape York and on the neighbouring islands. The collection consisted of sixty-one skins referable to thirty-eight species, all, or nearly all, of which belonged to well-known Australian forms, one or two only being uncertain on account of the immature condition of the specimens.—A communication was read from Mr. Francis Nicholson, F.Z.S., in which he gave an account of a small collection of birds made in the neighbourhood of Abeokuta, West Africa. Amongst these was a new species of Finch which was proposed to be called *Amadina sharpei*.—The Rev. S. J. Whitmee, C.M.Z.S., read a paper on the mode of the modifications of anger, fear, &c., in fishes, and on the use of their spines, as observed by him during his residence in the Samoan Islands.—Messrs. P. L. Sclater and O. Salvin gave an account of the collection of birds made by Prof. Steere during his recent journey across South America, from Para to Callao. The 911 specimens obtained were stated to be referable to 362 species, of which five were described as apparently new to science, and proposed to be called *Oryzoborus atrirostris*, *Myiarchus semirufus*, *Furnarius pileatus*, *Capito steerii*, and *Crypturus transfasciatus*.—Prof. Garrod read a note on the anatomy of the Binturong, *Artictis binturong*, and the fourth portion of his series of notes on the anatomy of passerine birds. —Mr. Howard Saunders, F.Z.S., read a paper on the subfamily of the *Larinæ*, or Gulls, being a monographical revision of the group, which he considered to consist of the genera *Pagophila*, *Rissa*, *Larus*, *Rhodostethia*, and *Xema*, containing altogether forty-nine species. With regard to *Pagophila*, he drew attention to a structural peculiarity which appeared to have been previously unnoticed, *i.e.*, the junction of hallux to the inner toe by a serrated membrane. Mr. Saunders also remarked upon the occasional presence of a small but well-developed hind toe and claw in individuals of the Kittiwake (*Rissa tridactyla*) from Alaska.—A communication was read from Mr. Martin Jacoby, containing descriptions of some new species of phytophagous coleoptera.—Two communications were read from Lieut.-Col. R. H. Beddome, C.M.Z.S. The first gave a description of a new form in the family of Tree-agames from the higher ranges of the Anamallays, proposed to be named *Lophosarea anamallayana*. The second contained the descriptions of some new species of *Uropeltidæ*, from Southern India.

Anthropological Institute, February 12.—Mr. John Evans, D.C.L., F.R.S., president, in the chair.—Mr. H. C. Sorby, F.R.S., read a paper on the various colouring matter met with in human hair. In this paper the author described the manner in which the various coloured substances met with in human hair may be separated and distinguished. Four quite different and well characterised pigments have been obtained, but of these two serve to modify the tints of hair to only a very limited extent. The general colour is mainly due to a black and a brown-red pigment, both of which can be easily obtained in a separate form, and used like water colours, as shown by the numerous drawings which were exhibited. All the varying tints of black, brown, dark and lighter red, and most of the pale tints are easily proved to be due to a variation in the total and relative amounts of these two substances as shown by a series of comparative analyses. The paper concluded with some remarks on the bearing of these facts on ethnology, and with a consideration of the probable explanation of certain changes in the colour of hair occasionally met with, but not yet fully understood.—The Director then read a paper by the Hon. Chas. C. Jones, jun., on bird-shaped mounds in Putnam County, Georgia.

Meteorological Society, February 20.—Mr. C. Greaves, F.G.S., president, in the chair.—Dr. Tripe read a paper on the winter climate of some English sea-side health resorts. The places selected were Scilly, Torquay, Penzance, Guernsey, Barnstaple, Ventnor, Llandudno, Ramsgate, and Hastings, and the climatic features of each were compared with those of London. The results of this discussion may be briefly summed up as follows, viz.:—The mean daily winter temperature of these seaside places, and especially of those situated on the coast of Devon and Scilly, is higher than at London; the mean daily maxima and minima are also higher, and especially the latter; so that the daily and monthly ranges of temperature are smaller; the mean humidity is less, the general direction of the wind about the same, but the number of rainy days and the rainfall are greater at the sea-side. As regards the wind, therefore, the chief point to be especially noticed is the amount of shelter afforded by high land, as at Ventnor, and especially of protection against the stormy and cold winds which ordinarily prevail at the end of February and in March. The soil also should be considered, as heavy rains at gravelly and chalky places are not so objectionable as on clayey ground.—The discussion on this paper was adjourned until the next meeting, which will be held on March 20.—The following were elected Fellows of the Society:—W. C. Baker, W. Berridge, W. M. Burke, Rev. J. A. L. Campbell, Prof. J. Eliot, Lieut. C. S. F. Fagan, C. H. Holden, Prof. H. J. S. Smith, Capt. W. Watson, C. Woollett, and Miss E. A. Ormerod.

Institution of Civil Engineers, February 12.—Mr. Bateman, president, in the chair.—The paper read was on the evaporative power of locomotive boilers, by Mr. J. A. Longridge, M. Inst. C.E.

PARIS

Academy of Sciences, February 18.—M. Fizeau in the chair.—The President gave an account of the funeral of M. Claude Bernard on the 16th inst., and the discourses pronounced by MM. Dumas, Mezières, and others. (These are published in the *Comptes Rendus*.)—Meridian observations of small planets at the Greenwich and Paris Observatories during the fourth quarter of 1877, by M. Villarceau.—On some applications of elliptic functions (continued), by M. Hermite.—Experimental researches on the fractures traversing the earth's crust, especially those known as joints and faults (continued), by M. Daubrée. His object is to show that torsion may account for many of those effects.—Tibio-calcanean resection, by M. Sedillot.—Refutation of M. Pasteur's criticism of his opinion as to the origin of alcoholic yeast and lactic yeast, by M. Trécul.—The vibrations of matter and the waves of the ether in vision, by M. Favé.—Remarks on the satellites of Mars, by M. Roche. He considers the first satellite comparable to the inner ring of Saturn in its origin; it owes its existence (as satellite) to being a little more separated from its planet.—On the law of reciprocity for invariants and covariants of binary quantics, by Prof. Sylvester.—On MM. Clebsch and Gordon's theory of associated forms, by the same.—Presence of magnetic spherules similar to those of atmospheric dust, in rocks belonging to ancient geological periods, by MM. Meunier and Tissandier. If the identity be admitted, we must infer that the layers of the earth's crust contain materials of cosmic origin which fell in a very distant epoch (such particles are found in the Devonian series). It is important to determine where they first appear.—On the vibratory forms of solid and liquid bodies, *à propos* of a note by M. Dubois, by M. Decharme. A claim of priority.—Separation of the non-ferruginous elements of rocks, based on their difference of specific gravity, by M. Thoulet. The specific gravity of most of the essential minerals of rocks varying between 2·2 and 3: these may be separated from each other by immersion in solutions which are without chemical action on them, but whose specific gravity is comprised between the same limits. Such are solutions of iodide of mercury in iodide of potassium. (Details of the method are given.)—On the state of phylloxerised vines in the commune of Mezel (Puy-de-Dôme), by M. Truchot.—Theory of Vesta: perturbations dependent on the first power of the perturbing masses, by M. Leveau.—On the special conditions in the contour of plates, by M. Boussinesq.—On the conditions for a quadratic form of *n* differentials to be transformed so that its coefficients lose a part or the whole of the variables they contain, by M. Levy.—On the summatory formula of Maclaurin and interpolar functions, by M. Genocchi.—On Bell telephones and string telephones, by M. Breguet. By attaching a string telephone (with parchment membrane) to any point of a Bell telephone, one may hear through it a person using a Bell telephone. Several string telephones may thus be connected. A mode of making the string telephone more practicable is described.—On telephony, by M. Salet. A telephone is described in which the movements of the two membranes are absolutely correspondent, the great electric resistance of liquids being utilised for the purpose.—On the ebullition of superposed liquids, by M. Gernez.—Extraction of gallium, by MM. Lecoq de Boisbaudran and Jungfleisch. The authors had obtained 62 grammes of metallic gallium by treating 4,300 kilogrammes of Bensberg blende (the method is described).—Method of volumetric determination of potash, by M. Carnot.—Dissociation of hydrate of chlorine, by M. Isambert. With regard to solubility of chlorine in water, he says that under 9° it is only the hydrate that is formed and dissolved in the water; above this temperature, at ordinary pressure, there is merely a solution of a gas in the water. Air passed through a solution of chlorine under 9° gradually carries off all the chlorine, as if there was solution and not combination.—Action of chloride of benzoyle on leucine, by M. Destrem.—On the identity of muscular inosite and vegetable sugars of the same composition, by MM. Tanret and Villiers.—On the preparation of amylene, by M. Etard.—Experimental researches on the maturation of the grape, by MM. Saint Pierre and Magnien.—On some volatile products of coal-pits set on fire, by M. Mayençon. He examined efflorescences round the fumeroles (the pits were in the Loire valley). The most abundant substances are ammoniacal compounds, arsenic, aluminium, iron, chlorine, and sulphur.—On the conditions of development of ligula, by M. Duchamp.—Sensations of light and colour in direct and indirect vision, by MM. Landolt and Charpentier.—On the geological constitution of the Island of Réunion (first part), by M. Velain. The succession of volcanic phenomena seems to be similar to that at Santorini.—Origin and distribution of limestone in maritime sands, by M. Contejean.—Barometric differences between neighbouring stations according to the direction of the wind (continued) by M. Renou.—On the flash of lightning which caused the burning of the belfry of Toucy (Yonne), on January 25, by M. Roché.

THURSDAY, MARCH 7, 1878

REPRESENTATION OF SCIENCE AT THE PARIS EXHIBITION

WE are glad to know that the interest shown in the Loan Collection of Scientific Apparatus at South Kensington and the benefit to the nation at large to be derived from such displays have not been lost upon the organisers of the French part of the forthcoming Exhibition.

Among the most energetic and most enlightened of these organisers we must count M. Bardoux himself, the new Minister of Public Instruction, under whose auspices for the first time a well-developed scientific side will form part of an International Exhibition. Culture will be added to industry. Research will have its place, side by side with the applications of science.

The attempts to give prominence to this side of the exhibition on the part of the French are as remarkable as the complete neglect of everything touching science by our own Commission. For them apparently science does not exist, except the science that pays, in the shape of large engines and looms, fine stuffs, machine-made jewellery, and the like. England will have its Burlington Arcade, but not its Burlington House. We give the Commission credit for having "worked" the commercial world well; we only complain that the possibility of there being anything worth exhibiting from the scientific point of view never seems to have occurred to them.

The antithesis we have drawn between the Burlington Arcade and Burlington House well represents the great point of the forthcoming Exhibition. There will be a gigantic shop on the Champ de Mars, there will be a gigantic temple devoted to the pure sciences and to pure art in the Trocadero. The river will separate the source from the application; instruction in science and art from commerce and industry.

Hence it is that M. Bardoux, having already organised on a large scale the representation of the fine arts and public instruction, is now organising what is to be called the "scientific display." This part of the work, important though it be, will be rendered very simple to the Minister, as the matter will be left almost entirely in the hands of the men of science themselves, including, of course, those men of science who direct important branches of the public service as well as individual investigators.

Thus each Government department will show the way in which its scientific work is done. The three new Government observatories in Paris will exhibit either results or methods. There will be a complete collection illustrating the various scientific missions which France has undertaken during the present century, and all the publications, scientific, historic, and artistic, which have been published by the state will be there for all the world to see.

Not only, therefore, will there be a true Loan Collection of Scientific Apparatus, but the example set by the South Kensington Conferences wills also be followed. The enormous building in the Trocadero contains a lecture theatre capable of holding upwards of 4,000 people. This will be used for lectures in scientific and kindred subjects, for which arrangements are now being made. It is impossible that the Trocadero buildings can be ready by May 1, so there will be ample time for these arrangements and for the others, to which we may briefly allude.

The French Association for the Advancement of Science will conduct a large number of scientific experiments on a great scale, and a large number of exhibitors will take advantage of the meeting of that association to exhibit experiments relating to their special pursuits.

Every facility will also be given to scientific societies for summoning to a special congress those prosecuting the same line of research. The number of these useful assemblies is increasing daily. It would occupy too much space to give a list of all the societies which will hold such meetings, but many circulars illustrating the development of this sectional movement have already been printed.

Lecture-rooms will be furnished *gratis*, lectures will be advertised on a large scale, and, as far as possible, Government apparatus will be at the disposal of inventors for conducting the experiments required to illustrate their lectures. What has been done at the provisional Ethnographical Museum, to which we have already referred, may be considered as a fair specimen of what will be done on a larger scale at the Trocadero Palace and other suitable buildings.

It may be said that nothing will be spared to make the Exhibition useful to science and intelligible in its scientific aspects for the largest number of people.

Surely England might have been able to contribute something of interest to this most interesting side of the Exhibition? We surely must, after all, be merely a nation of shopkeepers seeing that our Royal Commissioners have doubted our capabilities in any other direction!

METROLOGY

Inductive Metrology; or, The Recovery of Ancient Measures from the Monuments. By W. M. Flinders Petrie. (London: Saunders, 1877.)

THIS work has a somewhat ambitious title, but it may fairly claim to be written upon a scientific basis, and it bears evidence of much study and laborious research. It is an attempt to carry out generally the method originated by Sir Isaac Newton, in his well-known Dissertation on Cubits, of determining the length of the ancient Egyptian cubit from some of the measured dimensions of the great pyramid. By a similar process the author has endeavoured to determine the ancient standards of linear measure in various countries from the measurements of remaining monuments. No allusions are made to weights and volumes, but only to linear quantities, as these alone are shown by the architectural remains.

In accordance with Whewell's definition of "induction," Mr. Petrie says that "inductive metrology ascertains the 'general truths' of the units of measure in use from the 'particular facts' of those multiples of measures which ancient remains preserve to us." He assumes that in the construction of all such works, if a measure existed, it would be used, and that whole numbers would be used in preference to fractions and round numbers in preference to uneven ones, merely for convenience in the work. We know this to have been the case with regard to the various dimensions of the tabernacle constructed by Moses, of Solomon's Temple, and the later temple as described by Ezekiel, The length of the Royal Egyptian Cubit was determined by Sir Isaac Newton, from Greaves's measurements in the great pyramid, to have been between 20·62 and 20·78 English inches. Amongst these measurements the so-called King's Chamber was found to be 20 of such cubits in length, and 10 in breadth. The passages were 2 cubits broad. The principal gallery was 4 cubits broad, with a middle way of polished marble 2 cubits broad, and a raised bench on each side 1 cubit broad and 1 cubit high. In Newton's time, no direct evidence of the true length of the ancient Egyptian cubit had been brought to light. We now know from several ancient standard cubit rods since discovered, that the mean length of the royal Egyptian cubit was equal to 20·67 English inches. In this essay Mr. Petrie states that all the deduced units of measure were in every instance found in a similar way independently of any known standard, and have not been obtained by trying whether the measures would fit any known unit. As to standards of measure, they are only employed by the author to subject assumptions to proof, where such can be obtained.

The least number of measurements that suffice to give a unit with tolerable certainty is assumed to be three. Long lengths were found of little value in obtaining the unit, and moderately short lengths from about 2 to 20 feet are stated to be the best. After showing the several modes of ascertaining as nearly as may be the unit of measure from a given number of actual measurements, that is to say, the ratio between them, the process adopted has been to group together those units of any one country and age that seemed to be identical, or derived from and related to one another, and thence to deduce the mean unit. In every case the probable error has been computed and stated. This probable error is assumed to arise from original errors in planning and executing the work, and not in the more recent measurements, as with reasonable caution such errors may be tolerably avoided.

The extent of the work undertaken by the author may be judged of from the statement that more than 600 buildings and other remains have been examined and their constructors' units deduced from the mean results of over 4,000 measurements. A considerable number of them were made by the author, many being of objects in the British Museum. To insure correctness the English measure used by him was verified as to its accuracy at the Standards' Office.

The first series of groups relate to Egyptian architectural remains, generally from the fourth dynasty to the Roman period. The deduced units of the measurements of 101 monuments are stated in English inches and decimal parts of an inch, and the number of independent lengths from which each such unit was obtained is also specified. The deduced units of one of these groups, consisting of twenty-eight different monuments vary only from 20·42 to 20·84 inches, the mean being 20·64, thus agreeing very nearly with the ascertained length of the royal cubit = 20·67 inches. From the remaining monuments the author deduces other units several of which are multiples of the digit, the twenty-eighth part of the royal cubit. The common cubit, or cubit of a man, equal to 18·24 inches, has not yet been found inductively from remaining monuments.

The next series of monuments examined are those of Babylonia and Assyria, Persia and Syria. These countries are classed together as being intermixed in the style of their art and the nature of their architectural remains. The results of the measurements of 102 monuments are given, with various deduced units of measure. The Persian monuments are chiefly those of Persepolis. It may be more interesting to refer to the Syrian monuments as they include those of Judæa and Palestine, and of Moab. As an instance, the mean unit of 25·01 inches (varying from 24·57 to 25·55 inches) is found from six monuments, four of which are at Jerusalem. This is taken to be the mean length of the sacred Jewish cubit. It is to be observed that in his "Dissertation on Cubits," Sir Isaac Newton arrived at the conclusion that the length of this cubit was 24·83 inches. It is now generally considered to have been a little more than 25 inches, and it is supposed to have been the cubit measure taken from Chaldæa by the ancestors of the Jews, and to have continued in use by their posterity in Egypt and Palestine.

The countries that follow are Asia Minor and Greece. The first of these affords eleven different units from eighty-four measured monuments. Eight of these units are known to have been used by nations that ruled there, and the other three are connected with the units of adjacent countries. From Greece and its colony Sicily the results of the measurements of forty-nine objects are given, including Pelasgic and later monuments.

Italy, Africa, and Sardinia are next classed together. The results of the measurements of seventy-seven monuments are shown under the head of Italy, including Roman remains in Britain, Africa, and other countries probably constructed with Italian units of measure.

The mediæval remains in Ireland and England conclude the several classed groups of monuments measured. The measurements of twenty-nine round towers and churches connected with them in Ireland give two deduced units. Out of eighty-one measured old English remains the inch and foot were found to be the units in sixteen cases only, the mean inch unit being equal to 0·9998 of our present standard inch, showing that on the average the inch measure has not varied appreciably for centuries. Several other units of other countries are deduced from the remaining monuments.

The last series of measurements are those of rude stone remains and earthworks in various countries. At first sight it does not appear possible that such objects should lead to units of measure being derived from them; but the results show, in the author's opinion, that the more regularly constructed remains were made by a measure-using people.

After mentioning the results of measurements partly of the dimensions and partly of the relative positions of various ancient stone remains and earthworks in this country and in France, the results of about seventy measurements of the dimensions of ancient North American earthworks are stated to lead to a unit varying from 12·50 to 12·72 inches, with a mean of 12·6 inches, divided duodecimally. The mean unit of twelve Mexican measurements was 10·65 inches.

The author claims, as the chief results of his inductive examination, to have determined from the monuments the true values of the Sacred Hebrew or Royal Persian cubit, the Royal Egyptian cubit, the Egyptian digit, the Assyrian cubit, the ancient Greek foot, the Olympic foot, the Drusian foot, the Plinian foot, and the Pythic foot, together with the probable errors of these determinations.

He claims also to have found that the principal standard units of length were in more extended use than was previously known, and to have indicated the countries in which they were used. And also that he has brought to light many other units of length of which the knowledge had been previously lost.

It is not probable, however, that all persons who have given mature consideration to the contents of the work will concur in the stated results or be altogether satisfied with some of the mean units obtained. In every case a unit deduced from the actual measurements is stated, and not the measurements themselves. But a large proportion of these deduced units are not whole numbers of the mean unit obtained from them. Thus, taking one of the instances most favourable to the author's views, out of twenty-eight Egyptian monuments, from which the mean length of the royal Egyptian cubit is obtained, twelve only of the deduced units are whole numbers, the others being various fractions of the mean unit, and many of them, such as [illegible], [illegible], [illegible], $\frac{1}{10}$, $\frac{1}{12}$, $\frac{3}{8}$, $\frac{5}{8}$, $\frac{1}{50}$, [illegible] are fractions not marked upon any of the extant standard cubit rods, which are divided only into seven palms and twenty-eight digits.

The essay will be read with much interest and advantage by those persons who have given their attention to metrological science. It appears to be a valuable contribution to historical and ethnological literature, and to be a ground work for further researches on the subject.

HISTORY OF ASTRONOMY

II.

Geschichte der Astronomie. Von Rudolf Wolf. (München: R. Oldenbourg, 1877.)

IN our former notice of this valuable addition to astronomical literature (NATURE, vol. xvii. p. 259) reference was made to the great amount of information which the author has compressed within a moderate space in the third and last section of his work which treats of "the newer astronomy." We propose here to take a brief survey of the principal contents of this portion of the volume to assist the reader's appreciation of the work.

The third section is subdivided into four chapters—9–12. The first commences, as before stated, with Sir Isaac Newton's discovery of the principle of universal gravitation, the publication of the "Principia," and the first application of the new theory to the orbits of comets by Halley, whose meritorious connection with the publication of Newton's immortal work is well known. This is followed by some account of the foundation of the Observatories of Greenwich and Paris, and soon afterwards of those of Berlin and Copenhagen, whereby so great an impetus was given to practical astronomy; of Richer's expedition to Cayenne for the determination of the solar parallax, from corresponding observations of the planet Mars, and the first ideas as to the applicability of transits of Venus for the solution of the same problem. The labours of the earlier workers in the Newtonian theory—of Bernoulli, Euler, Clairault, and others, are particularised; also Bradley's great discoveries of the aberration of light and the nutation of the earth's axis, together with his work in the field of observation, with the similar work of Tobias Mayer and Lacaille. Further on the same chapter treats of the labours of Lagrange, Laplace, Gauss, and others in theory, and of Herschel, Piazzi, Bessel, Struve, and others, in the practice of astronomy. We have some account of the "Theoria Motus," the "Fundamenta Astronomiæ," amongst classical works, and of progress made in the solar, lunar, and planetary theories, and formation of tables and ephemerides. Amongst the remaining varied contents of this chapter there are notices of the discovery of Neptune, stellar parallax, the connection between solar spots and the earth's magnetism, the application of photography to astronomical purposes, and the introduction of the spectroscope.

Chapter 10 is devoted to astronomical instruments and their uses, after some remarks upon methods of calculation introduced in modern practice. There are brief notices of instruments in their various forms, from the complicated heliometer to the simpler appliances in the hands of observers, with descriptions of many of the more important purposes for which they have been brought into use. The chapter concludes with a reference to Lacaille's memorable expedition to the Cape of Good Hope and the expeditions undertaken on occasion of the transits of Venus in 1761 and 1769.

Chapter 11, on "The Structure of the Heavens," is as varied in its contents, amongst which we may note: The periodicity of sun-spots, and the new views upon the physical constitution of the sun; the ring of small planets; the zodiacal light; the meteor-streams and their connection with comets; the physical condition of comets; the distribution of the stars; the Milky Way; solar motion in space; variable and double stars, and binary systems; stellar spectra, star clusters, and nebulæ.

In Chapter 12 we have an account of the principal modern literature, periodical and otherwise, bearing upon astronomical science in its various branches. There are notices of the works of Weidler, Lalande, Bailly, Montucla, Delambre, Littrow, Madler, and others, and of such works as the *Acta Eruditorum*, the *Monatliche Correspondenz* and the *Astronomische Nachrichten*.

It should be understood that the one chief advantage which the student is likely to derive from Prof. Rudolf Wolf's "History of Astronomy" will be a knowledge of the authors, methods, &c., with which it may be necessary for him to become acquainted in turning his attention to any particular department of astronomy, an advantage that may not be immediately apparent from the title of the work. Prof. Wolf does not enter into any amount of detail, nor indeed would it have been practicable within the limits of this volume. But as affording in comparatively brief space an accurate idea of the gradual progress and actual state of astronomical science and a valuable guide to any one entering upon its study, this book may be confidently recommended. J. R. HIND

OUR BOOK SHELF

The Spectroscope and its Work. By Richard A. Proctor. Society for Promoting Christian Knowledge. (London : 1877.)

In a little work of 127 pp. Mr. Proctor has clearly and logically explained the principles of the science of spectroscopy, and has given a sketch of the main results of spectroscopic research into the nature of the sun, stars, and nebulæ.

One of the features of this book is, we think, the logical manner in which the principles of spectroscopic analysis are developed from the facts gained by observation and experiment ; the steps of the various reasonings are succinctly but clearly stated ; this is a point of much importance. In too many so-called scientific text-books there is a loose and illogical method of connecting facts, and conclusions drawn from these facts ; by the perusal of such books the general reader is either strengthened in his prejudged conviction that science teaching is of little or no value as a mental exercise, or he is taught, often almost unconsciously, to believe that the generalisations of science and the facts of science rest upon exactly the same evidence. Another feature in Mr. Proctor's little book is the adoption, necessarily to but a limited extent, of the method of historically developing the facts of the science of which he treats. The leading steps in the history of the most important advances in spectroscopy are traced, frequently by quotation from the classical memoirs of the great workers in the science.

The book is divided into eight chapters, headed respectively "Analysis of Light," "Dark Spaces in the Spectrum," "Various Order of Spectra," "Interpretation of Solar Spectrum," "Solar Prominences, &c.," "Spectra of Stars, &c.," "Atmospheric Lines in Solar Spectrum," "Measuring Motions of Recession and Approach."

Whether as an introduction to the fuller study of spectroscopic analysis, or as a work from which the general reader may gain a clear, and, so far as it goes, complete view of the science, Mr. Proctor's work is deserving of the warmest recommendation.

M. M. PATTISON MUIR

The Great Thirst Land ; a Ride through Natal, Orange Free State, Transvaal, and Kalahari Desert. By Parker Gillmore. (London : Cassell, Petter, and Galpin.)

CAPTAIN GILLMORE'S work is disappointing. The title suggests Major Butler's "Great Lone Land," but the result of a comparison of the two works would not be very favourable to Capt. Gillmore's. He has nothing new to tell the geographer, and many of the hunting stories are comparatively tame. The work is unnecessarily large, and could with advantage be compressed to half its present size. Still there are a number of observations on the Boers and the natives which will interest many, and there are a few good lion stories. The book is handsomely got up.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Strychnia and its Antidote

THE following circumstance I think worth noticing. Wanting to banish some mice from a pantry, I placed on the floor at night a slice of bread spread over with butter in which I had mixed a threepenny packet of "Battle's vermin killer," which contains about a grain of strychnia along with flour and prussian blue. The following morning I was roused by a servant telling me that a favourite skye terrier was lying dead. I found that the mice had dragged the slice of bread underneath the locked door and that the dog had thus got at it and eaten part equal to about one-sixth of a grain of strychnia ; it lay on its side perfectly rigid ; an occasional tetanic spasm showed that life was not quite extinct. Having notes of the experiments made by direction of the British Medical Association last year, on the antagonism of medicines, and wherein it was conclusively proved that a fatal dose of strychnia could be neutralised by a fatal dose of chloral hydrate, and that the minimum fatal dose of the latter for a rabbit was twenty-one grains, I at once injected under the dog's skin forty-five grains of the chloral in solution, my dog being about twice the weight of a rabbit. In a quarter of an hour fancying the dog was dead, as the spasms had ceased and it lay apparently lifeless, I moved it with my foot, when it at once struggled to its feet and shortly after staggered to its usual corner by the parlour fire ; it took some milk, and except for being quieter than usual seemed nothing the worse for the ordeal it had passed through.

That the fatal effects of a poisonous dose of strychnia was thus counteracted so successfully by what I should say was a poisonous dose of chloral, given hypodermically, is an interesting fact verifying the experiments I alluded to. Without such experiments on the lower animals, a medical man might often be found standing by helpless to aid his fellow man under similar effects of poison.

Sudbury, Suffolk, February 27 J. SINCLAIR HOLDEN

Age of the Sun in Relation to Evolution

I THINK I may be permitted to point out that Dr. Croll has missed what I had intended to be the main feature of my criticism of his article on the "Age of the Sun in Relation to Evolution." I should therefore wish to reiterate that, in his theory, he takes no account of the proper motions of the stars in space. If it be true that suns or stars have been formed by the collision of bodies possessed of great energy, proper motion can be none other than the unused and unconverted energy of the original components. Supposing the forces, before impact, to be equal and opposite in direction, there can be no misunderstanding that the result will be the *entire* convertion of the "motion of translation to molecular motion," *i.e.*, heat ; but this, according to the law of chances, must be of exceedingly rare occurrence. Yet, from our knowledge of the motions of the stars in space, this, or something very like this, has invariably occurred. Surely here is a *reductio ad absurdum*. In conclusion I will merely state that I have never yet claimed to have suggested a theory reconciling the age of the sun with prevailing opinions in geological science or with the hypothesis of evolution. Having felt the difficulty, I have endeavoured in some measure to stretch the interval wherein these may have had time to effect their changes, but I have not claimed to have succeeded to the desired extent. I am not, therefore, interested in replying to the former part of Dr. Croll's letter, and indeed, with certain minor reservations, have no hesitation in subscribing to it.

JOHN J. PLUMMER

Orwell Dene, Nacton, February 28

The Zoological Station at Naples

PERMIT me to correct some statements made in NATURE, vol. xvii. p. 329. The small steam launch was given to the Zoological Station by the Berlin Academy of Science, in exchange for a working table in the laboratory, which is to be placed at the disposal of the Academy for ten years. The Prussian government subscribed 300*l.* towards the expenses of the launch, which was built by Messrs. J. Thornycroft, Church Wharf, Chiswick, and has proved an excellent little craft.

As to the publications of the Zoological station, the *Prodromus Faunæ Mediterraneæ* will be a compendium of all the species hitherto observed in the Mediterranean, and recorded in scientific works. Its publication is mainly intended to facilitate the nomenclature of the chief work, the "Fauna and Flora of the Gulf of Naples and the Neighbouring Seas," which is to appear in monographs. The *Prodromus* has been undertaken by Prof. T. Victor Carus, whose great knowledge both of zoological literature and classification will answer its exactitude and completeness

The first monograph to be published is not on the *Elanophora*, but on the *Ctenophoræ*, a family well known to all students of pelagic animals. ANTON DOHRN

Naples, February 28

Faraday's "Experimental Researches"

IF your readers will compare Mr. Quaritch's letter in last week's NATURE with his advertisement of the two preceding weeks, they will see that it bears its condemnation on its own face. No words of mine can make it plainer than his do, that a *reprint* of an obsolete and valuable book was offered to the public as something not stated to be a reprint. Had that advertisement stated that the work was a "facsimile reprint," there could have been no ground either for complaint or for an indignation for which no apology is needed.

University College, Bristol SILVANUS P. THOMPSON

Mimicry in Birds

ON the evening of the 24th inst my attention was attracted by an interesting example of mimicry in the case of the starling. The first thing which attracted my attention was hearing the cry of a blackbird in distress, and on looking round, the only bird to be seen was a solitary starling, which, when I first observed it, was uttering its own note; but almost immediately thereafter it began to whistle loudly in imitation of the blackbird. After this, for the space of about half an hour, it kept up a constant succession of notes in mimicry of the chaffinch and sparrow, always, however, using its own note for the space of about half a minute between each change. I may add that it did not seem to have any particular order in which it repeated the various notes.

A gentleman in this neighbourhood tells me that last year he observed a similar occurrence in his garden; but this, so far as I can learn, is the only other instance of similar mimicry in this quarter. Perhaps some of your readers may be able to inform me if it it is of common occurrence elsewhere.

Edinburgh, February 26 J. STUART THOMSON

Great Waterfalls

SEEING Mr. Guillemard's inquiry (vol. xvii. p. 221), I refer him for accounts of the Falls of Tequendama, which I visited in 1851, to "Viajes Cientificos a los Andes Ecuatoriales, &c.," por M. Boussingault, traducidas por J. Acosta; Paris, 1849, and "New Granada. Twenty Months in the Andes," by Prof. Isaac F. Hotton. (New York: Harper and Brothers, 1857.)

New York, February THOS. BLAND

SEVERAL NEW APPLICATIONS OF SCIENCE INTRODUCED INTO WAR

ON Saturday last, the Speaker of the House of Commons and a large following of members, visited the Portsmouth Dockyards, mainly for the purpose of witnessing some torpedo warfare; the *Inflexible* was also inspected. Near the starboard side of the ship, one of the sheds had been converted into a temporary lecture-room, and provided with numerous diagrams, a model of the ship, and a full-sized skeleton model of the 80-ton gun, 26 feet long, 6 feet broad at the breach, and having a calibre of 16 inches, with four of which it is intended to arm the turrets of the *Inflexible*. The diagrams were drawn on a scale of one-fourth of an inch, half an inch, and 6 inches (half-size) to the foot, and were designed with the object of enabling the visitors to draw a comparison between the structures of the *Dreadnought* and the *Inflexible*, and the respective thicknesses and disposition of their armour. As soon as the party had assembled around the drawings, Mr. W. B. Robinson, the Chief Constructor of the yard, stepped forward and delivered a brief illustrative lecture on the main points and differences of the two ships. He pointed out that while the length of the *Inflexible*—320 feet—was exactly the same as the *Dreadnought*, its beam—75 feet—was 11 feet 2 inches broader; that its volume of displacement was greater, its armour heavier, its turrets thicker, and its armament more formidable. While, however, the *Dreadnought* was armoured along the water-line, the citadel of the other ship, which was placed upon an armoured deck below, was the only protected portion of the *Inflexible* above the water. The arrangements of the turrets was also different; for whereas those of the smaller ship were placed along the middle line, the turrets of the larger were *échelonned* to starboard and port in order that all the four guns might be trained upon an enemy either direct ahead or direct astern. The weather deck between the turrets had also been raised, so that the guns could be loaded from below without the necessity of depressing their muzzles. She was supplied with steam and hand pumps, and with Friedland's injectors, which would enable her to discharge 5,300 tons of water an hour. She had 133 water-tight compartments, and water would be admitted into the double bottom to reduce the rolling of the ship. Her torpedoes would be discharged from submerged ports in the bows instead of from above the water in the side, as in the *Thunderer*. The ventilating arrangements will be of the most perfect kind; for, as Mr. Robinson remarked, while in the other ships the fresh air is pumped into all parts, no means are adopted for assisting the vitiated atmosphere out of the ship. In the *Inflexible*, however, the ventilation comprises both supply and exhaust arrangements. The air is brought down into an air chamber, or cave of Æolus, in the central part of the citadel, and is driven thence by steam fans through large pipes, which pass under the armour deck and up into the structures above, and by means of branch pipes fitted with cocks every compartment in the ship can receive an abundant supply. By these cocks an officer can regulate his air supply in much the same way that a householder on shore can regulate his water supply. The vitiated air is sucked up through pipes with perforated ends into the funnels, and thence through the citadel into the open air. The *Inflexible* will be brig-rigged, but her masts will be unshipped before going into action. Her engines are of 8,000-horse power, and she is expected to attain a speed of 14 knots.

Runs of the 16-inch Whitehead torpedo were next made. One was fired from a steam pinnace as in actual warfare, its course, which was in a straight line for about 200 yards, being distinctly traceable by the exhaust air-bubbles which it threw up. The other was discharged from the surface of the water for the purpose of showing how readily it sank automatically to the required depth. The next novelty submitted was the steam pinnace, which, without having a single man on board, can do everything but stoke and keep its own fires alight. Its engines are worked and its movements are controlled wholly by electricity, the cable which supplies it with its mysterious power being unwound from winches as the pinnace sails on its mission, "And drags at each remove a lengthening chain." Its principal use is to drop and explode countermines in the neighbourhood of an enemy's mines, and by destroying them clear a harbour for the approach of the fleet. It performed its work to the amazement of the beholders on Saturday. The countermines were represented by a couple of barrels containing small charges of gun-cotton, and with these slung over the sides it took its departure from the boat containing the battery and dropped the casks at a distance of about 200 yards, igniting at the same time the fuses which blew the barrels into match-wood, and returned obediently, like a "thing of life," to the controlling hand after having accomplished its duty. Near at hand in the basin the torpedo nettings for protecting ships against the locomotive torpedo were exhibited on the sides of the *Actæon*, while the prow of the *Bloodhound*, gunboat, was armed with the trawl with which it is proposed to pick up sunken mines. The notes of the bugle were next heard as a summons to quarters and for the *Thunderer* to be cleared for action. In an incredibly short space of time the stanchions and guard-rails were flung down, the water-tight doors closed, and the couple of Gatling guns dismounted from their carriages on the superstructure deck and hoisted up to the *tops*, whence they could each discharge 200 shots per minute upon hostile boats. Presently the process of loading the guns was gone through, in the fore turret by hydraulic power, and in the after turret by hand gear; the turrets were rotated and the guns run out, and the snapping of the tube fuses told the spectators that a furious action had commenced.

The party was next conveyed to the *Vernon*, torpedo school, where Capt. Arthur and Commander Wilson had still more surprising wonders in the art of warfare for them to witness. First of all, Commander Wilson delivered a hurried lecture on the mysteries of torpedo science, explaining the differences between offensive and defensive torpedo warfare, the nature of the several explosive substances used, and the methods of firing torpedoes—mechanically, by means of glass tubes of sulphuric acid, which explode on coming in contact with chloride of potash, or glass tubes filled with potassium, which causes explosion on mixing with the water, or, electrically, by means of detonation produced by fulminate of mercury. Commander Wilson also showed by means of a model in a tank the method of ascertaining when a ship is over a sunken torpedo by means of cross bearings, and how the mine is fired as soon as the telescope which is following the movements of the ship completes the electrical circuit. As the model, however, did not sink with great alacrity in its mimic ocean, Commander Wilson explained that the torpedo did not profess to destroy a ship instantly, but only to knock a hole in the bottom about the size of a barn door. At the conclusion of the lecture the company again went on deck, and saw discs of dry and damp gun-cotton harmlessly consumed, and how a solid block of wood could be shivered by the same material when exploded with a detonator. Next, on looking over the bulwarks, they beheld a practical illustration of the boat's crew "creeping" for an enemy's torpedo, the process consisting in dragging for the mooring chains, and, when found, destroying them by a discharge of gun cotton. They were also shown the manner of attack with star torpedoes, firing lines of counter mines by "bumping" the circuit closer, and, lastly, how attacking boats can be destroyed by grenades fired by fuses held in the hand. These beautiful experiments closed the day's programme.

We are glad that so large a body of our legislators were present, and we are sure they could not fail to be impressed with the importance of science in its bearing on war. In fact it has become clear that the more war we have, or are likely to have, the more is science needed; and it would indeed be a very short-sighted policy for Government to cut down the very moderate supplies allowed to science for the purpose of providing war expenditure. We hope that after what they saw on Saturday the members of the House of Commons will have a higher opinion of the national value of scientific research than to adopt any such course.

METEOROLOGICAL NOTES

TORNADO IN CHESTER COUNTY, PENN., U.S.—Mr. Richard Darlington, of Ercildoun Seminary, has published an account of a remarkable tornado which swept over this portion of the United States on Sunday, July 1, 1877. The tornado appears to have been first felt a little to westward of the boundary line between Chester and Lancaster Counties, and to have thence run a course of twenty-two miles, first in a direction E. 20° S., then E. 15° S., and lastly, E. 7° S., moving bodily onwards at rates of from five to fifteen miles an hour, the average progressive movement being twelve miles an hour. The destruction of trees, houses, and other property is estimated at about 40,000 dols., the destruction being most complete in those cases where the tornado moved across a valley. An uninterrupted roar, like that of thunder, accompanied it during its whole course, which is sufficiently accounted for by the inherent energy of the tempest itself and the havoc it wrought throughout its course, such as twisting thick oak-trunks in two, tearing up tall trees by the roots, and whirling them aloft, and blowing down buildings and scattering their contents in all directions. The breadth of the tornado varied from 100 to 300 feet, the average being 200 feet, though the *débris* was scattered to a greater distance on either side. It appears to have originated between a south-west and a north-west wind, where a large dark cloud seemed to form in the atmosphere, suspended from which was a whitish funnel-shaped cloud whirling round in a terrible manner. The air was thick with the objects which were whirled aloft, the movements of which closely resembled buzzards sailing round. The rotary movement was to the left, and the cone appeared to be a cloud of vapour nearly white, connected at the upper end with a smooth surface of cloud somewhat darker. The upper portion of the cone appeared to move in a straight line and at a uniform rate, while the tail or lower end frequently bent in different directions, as if swayed from its true course by the hills and valleys it crossed. No rain fell in its track, but hailstones of a large size and in great quantity fell at intervals along its north side. Trees in the northern half of the track were generally thrown down with their tops to the south, while those on the southern side were thrown to the north; but at certain points, such as at Ercildoun, trees and other *débris* were thrown down in what appeared to be inextricable confusion. Some of the observers state that the *débris* ascended up the centre of the funnel-shaped cloud and fell back to the ground outside it, but the tornado was too sudden, brief, and appalling to admit of careful observations being made on this point, which is all-important in its bearing on the theory of tornadoes. No tornado is known previously to have traversed this part of the United States.

THE LAW AND ORIGIN OF THUNDERSTORMS. In the Christmas issue of the *Bulletin International* of the Paris Observatory, there is an interesting note on this subject by Prof. Ch. V. Zenger, of Prague. He has examined the thunderstorms which occurred at Prague during the ten years ending 1849, and those at Vienna during the four years ending 1875, arranging the dates of their occurrence according to the semi-solar days each period of observation embraced, there being twenty-nine such semi-solar days in each year. The general result is that, dividing the semi-solar day into three equal portions, 47 per cent. of the whole thunderstorms occurred in one of these portions, 32 per cent. in another, while only 21 per cent. occurred in the third. Prof. Zenger is of opinion that this result points to a cosmical origin for the thunderstorm, operating, no doubt, on pre-existing terrestrial conditions, an opinion which receives some countenance from the relation subsisting between thunderstorms and auroral and magnetic perturbations. The subject is of sufficient importance to call for a wider and more exhaustive treatment.

MONTHLY METEOROLOGICAL BULLETIN OF THE MONTSOURIS OBSERVATORY, No. 69.—This number gives the observations for August last, which now include, for the first time, the hourly velocities of the wind in addition to the hourly temperatures and rainfall, which were added some months ago. The daily minimum velocity of the wind, 7·2 miles per hour, for August occurred about 6 A.M., and the maximum velocity, 13·1 miles per hour, about 2 P.M., the increase in the wind's velocity being thus nearly doubled between these hours. These hours are all but coincident with the hours of mean minimum and maximum temperature. The table of the hourly amounts of the rainfall is a peculiarly valuable one. Several years must, however, elapse before its full value will be seen in determining the curve of the diurnal variation of the rainfall. We note, with much satisfaction, the continued prosecution of the important inquiry into the chemical climatology of Paris.

METEOROLOGY OF WESTERN AUSTRALIA.—We have recently received a most valuable addition to the meteorology of Australia, which is being so energetically worked out by Messrs. Todd, Ellery, Russell, and Macdonnell, in the form of a first Report of the Meteorology of Western Australia, by Mr. Malcolm Fraser, Surveyor-General for the Colony. The report contains a good summary of a pretty complete set of observations made during the whole of 1876 at Perth, and the barometric means for five months at Point King Lighthouse, on the south coast. The chief results are, for the summer months, mean monthly pressure 29·915 inches, temperature 74°·7, rainfall 0·54 inch, and wind velocity in miles 404; and for the winter months pressure 30·177 inches, temperature 57°·5, rainfall 4·90 inches, and wind velocity 280 miles. The lowest temperature for the year was 34°·7, and the highest 112°·0, on February 20, and it may be noted that the mean daily maxima for this month was as high as 93°·7. Speaking generally, the winds in summer blow from the sea inland, and in winter from the land seawards, little rain falling in the former season, whereas in the latter season the rainfall is copious but not excessive. The smallest rainfall of any month was 0·04 inch in February, falling on one day, and the largest 8·45 inches in June, falling on nineteen days. It is contemplated to establish stations at Nickol Bay, Champion Bay, and York; but a still further extension of the system is required, not merely for the development of the climatology of the colony, of which we may be said to know next to nothing, but also from the important bearing of the meteorology of Western Australia on that of the whole continent of Australia, particularly on the system of weather warnings for that group of colonies.

OUR ASTRONOMICAL COLUMN

THE URANIAN SATELLITES, ARIEL AND UMBRIEL.—We continue the ephemeris of the two interior satellites of Uranus, making use of Prof. Newcomb's tables in the appendix to the Washington Observations for 1873. The positions and distances are for 9h. Greenwich mean time, when the planet will be near the meridian during the period over which the ephemeris extends; though these are given for every evening, the presence of the moon in this quarter of the heavens may interfere with observation on or about March 16.

	ARIEL.				UMBRIEL.

THE TRANSIT OF MERCURY ON MAY 6.—The *Nautical Almanac* furnishes the usual elements of this phenomenon and the times of the contacts and of least distance of centres referred to the centre of the earth, with the necessary formulæ for reducing the moments of contact to any place upon the earth's surface. The following figures result for Greenwich, Edinburgh, and Dublin; Greenwich mean times at the respective observatories:—

	First External Contact. h. m. s.	First Internal Contact. h. m. s.
Greenwich	3 10 58	3 14 4
Edinburgh	3 11 0	3 14 6
Dublin	3 11 3	3 14 0

The least distance of the centres (4′ 47″) takes place at 6h. 58·5m. and, as the sun will set at 7h. 20m., 7h. 47m., and 7h. 36m. local mean times at these places respectively, rather more than half the transit will be visible. The final contacts may be well observed in America.

THE RADCLIFFE OBSERVATORY.—The Radcliffe Observer is again punctual in the distribution of his volume of Observations, Vol. xxxv., containing the work in the year 1875, having been in the hands of astronomers several weeks. The only new feature is the publication of observations of the solar spots; the distances from the sun's limbs are fixed by transits and by readings of the declination circle of the heliometer; descriptions and sketches of the forms of the spots are included. Nearly 1,200 stars were meridionally observed. At the end of the Introduction, Mr. Main has exhibited the apparent errors of Tabular R.A. of the moon's limbs, as given on the same day by the observers at Oxford and Greenwich in 1863 and 1864, and from 1870 to 1874 inclusive. As usual the meteorological observations taken at the Radcliffe Observatory are published in considerable detail.

THE HARVARD COLLEGE OBSERVATORY, U.S.—Prof. Pickering has issued a report of proceedings at this observatory during the year ended November 1, 1877, with an outline of the course of observations intended to be pursued in future with the 15-inch refractor and the meridian circle, the telescope of which has an aperture of eight inches. The newly-discovered satellites of Mars have been the objects to which most attention has been directed with the refractor, the observations consisting not only in a series of measures of positions and distances which Prof. Pickering believes to be second only to the very complete series obtained by the discoverer with the large Washington instrument, but in a numerous series of photometric comparisons with the planet on methods explained in the Report, by which the image of Mars was brought to the same degree of brightness as each satellite. It was remarked under favourable opportunities for comparison that the outer satellite did not partake of the red colour of Mars, which Prof. Pickering observes is "a curious result, and having an important value in any theory of the cause of the peculiar colour of Mars." The observations were not wholly reduced at the time the Report was issued, but an approximate reduction gave the diameter of the outer satellite about 5·9 miles, and that of the inner one, 6·5 miles. "As the darker colour of the outer satellite somewhat diminishes its light," it was considered safe to call it about six miles in diameter, and the inner satellite seven miles. These comparisons were made between August 27 and October 12. A large number of similar measurements of seven of the satellites of Saturn, including the very faint object, Hyperion, have also been obtained. Remarking that other classes of observation appear to be well cared for at various observatories in the United States (Dr. Peters being engaged in the determination of the small stars near the ecliptic, at Clinton; the great telescopes of Washington, Chicago, and Cincinnati, being used almost exclusively for micrometric measures; spectroscopy being the intended line of observation at Princeton College; and the telescopes of Mr. Rutherford and Dr. Draper being largely used for photographic purposes), Prof. Pickering intends to devote the Harvard refractor mainly to photometry as "a field almost wholly unexplored with large telescopes," in America or elsewhere. The meridian-circle appears to have been chiefly employed in the determination of stars to the ninth magnitude inclusive in the zone included between $+ 50°$ and $+ 55°$ of declination, undertaken at the instance of the Astronomische Gesellschaft, and this work approaches a conclusion. Upwards of 40,000 observations have been made with the meridian-circle since it was mounted at the end of 1870. The personal establishment at Harvard College now consists of Prof. Edward C. Pickering, as director, assisted by Prof. Rogers, and Messrs. Searle, Waldo, and Upton. Vol. x. of the *Annals* of the Observatory has been published during the past year. Vol. ix., with photometric observations 1872-75, is to follow, and is nearly ready for issue.

GEOGRAPHICAL NOTES

THE ALBERT NYANZA.—In his recent examination of Albert Nyanza, to which we have already referred, Col. A. M. Mason examined every inlet or indentation of the coast-line. Starting from Magungo in the s.s. *Nyanza*, Col. Mason followed the western shore, and found it overhung by lofty mountains, notwithstanding which there seemed to be a large population. On the first day the party reached Nurswar, and on the next continued their route to the south-west; after a six hours' run, they found that the coast-line trended more to the south, forming a wide plain, which in some places was covered with very heavy, thick forests. On the third day they crossed a wide bay to Kavalee. Soon after leaving Kavalee, Col. Mason found that the coast-line turned to the eastward, and in two hours' time they reached a mass of ambatch (like Signor Gessi), and found the south end of the lake very shallow. In the south-west corner Col. Mason noticed a second large bay, and from a depression in the mountains and a thick line of forest, he fancied that there might be a river emptying into the lake at that point, but he could find no entrance, and this accorded with what he had been told at Kavalee, that no river joined the lake near there. On the morning of the fourth day, after entering a number of small, shallow bights, he finally reached a broad river, the waters of which were reddish in colour, with a slight northerly current. The width of the stream is about 400 yards, the banks high and well-defined, and clothed with forests. Col. Mason was only able to proceed up this river for one hour, owing to the shallowness of the water, and there seemed to be a mass of vegetation blocking the way to the south; to the south-east he observed an immense forest of date-palms, and to the south and south-west an undulating country, covered with large trees. After leaving this river he found that he had crossed the lake, and that their course turned to the northward. On both sides of the lake the mountains were found to diminish in altitude, and to the southward, at the foot of the lake and between the two ranges, was a large isolated mountain, which was found to be in N. lat. 1° 11'. It is clear, therefore, that Lake Albert does not extend, as has been asserted, to the first parallel of north latitude. In his northward course Col. Mason found that the mountains were not so high as on the western shore, and that in only one place were the cliffs as lofty as the highest on the opposite coast. There was a marked difference, too, in the vegetation; on the western shore the mountains are well covered with timber and verdure, and in many parts the natives have cleared places for cultivation, while on the east the mountains are barren, with neither timber nor vegetation. On the fifth day the party passed several large villages, one of which was said to be the residence of Kava Gonza, brother to Kaba Rega, and, soon after, the village of Tiaboa was reached, above which the country is flat, and the coast-line trends to the north. From his observations Col. Mason found that Kavalee, near the south-west angle of Lake Albert, was in N. lat. 1° 22' 20", and the south-east angle in N. lat. 1° 11' 3".

MR. STANLEY'S WORK.—Mr. Stanley is engaged in writing a full account of his most important journey across Africa; and at present he is doing so with characteristic energy. Already a large portion of his manuscript is in the printer's hands, and his work will doubtless be ready for publication in May next. Mr. Stanley carried with him through the whole of his arduous journey a heavy photographic apparatus, and succeeded in obtaining many very good negatives of views and groups on the great lakes and on the Congo. The interest of these pictures can scarcely be over-estimated. They will be reproduced as full-page woodcuts in the volumes, which will also contain an unusually large number of vivid scenes and incidents from excellent sketches made by Mr. Stanley himself. Perhaps the most important feature of the work will be the chart of the Congo, which has been so minutely and elaborately mapped, that it will require a scale of an inch and a half to a degree to embody in the smallest writing the information conveyed. Besides this large route map, which will be in two parts, the work will also contain several maps of a valuable and interesting character. The work will be published simultaneously, the *Publishers' Circular* informs us, or as nearly so as can be arranged, by Messrs. Sampson Low and Co. in England; by Messrs. Harper and Brothers, New York; in French by Messrs. Hachette and Co., Paris; in German by M. Brockhaus, Leipsic; in Danish by M. Mallings, of Christiania. Negotiations are also pending for translations into the Swedish, Spanish, Italian, and Russian languages. The title is, "Through the Dark Continent; the Sources of the Nile; around the Great Lakes, and down the Congo." We are pleased to see that the *Geographical Magazine* of this month handsomely acknowledges that its previous hard judgment on Mr. Stanley's conduct was unjustifiable.

SOUTH-WEST AFRICA.—In his monthly summary, Dr. Behm refers briefly to an important journey made by two Rhenish missionaries last summer between the Cunane river and 21° south lat. They found that the coast mountains, opposite Wallfisch Bay, extend far to the north-west, with a height of from 4,000 to 4,500 feet. The travellers have noted many important details in their map which will form an important supplement to existing maps of Africa, as the region traversed is almost unknown.

AFRICAN DWARFS.—Dr. O. Lenz contributes to the *Mittheilungen* of the Vienna Geographical Society for January an important paper on this subject. He describes his own observations on the Abongo of the Ogové, whose average height is 133 152 centimetres. Dr. Lenz concludes that all the dwarfish African peoples—the Abongo of the Ogové, the Dongo of the Sette River, the Bakke-Bakke of the Loango Coast—are only part of an original great negro people, who are also found in the interior under various names—as Kenkob in the Lufum country, Mala-Gilagé in the south of Bagirmi; and further east, as Akka, Doko, Berikomo, &c.; and that this great people, who were perhaps the aboriginal inhabitants, the true autochthones of equatorial Africa, have been supplanted and destroyed by other migratory peoples. Dr. Lenz places the Bushmen in a similar category.

THE NORTH-EAST PASSAGE.—Prof. Nordenskjöld and Mr. Dickson of Goteborg, recently paid a visit to Hull in order to make various preparations for their intended Arctic expedition. It is also announced that Lieut. Sandeberg intends to organise a scientific expedition to Kolgajeff, the Petchora, Hvideö, and the Siberian coast during the approaching summer; he has already hired a vessel for this purpose, and intends to be absent for about six months.

DR. LENZ.—The well-known African traveller, Dr Oskar Lenz, has been presented with the cross of the Albrecht Order by the King of Saxony.

POPULAR NATURAL HISTORY[1]

WE have to congratulate the publishers of this fine volume on its appearance, for, on a careful perusal, it strikes us as very eminently fitted to supply a known public want. On one or two previous occasions the same firm have published large and well-illustrated works on natural history, the descriptive portions of which were, to say the least possible of them, not in any way up to the science of the day; but we have lately gladly witnessed an infinitely more careful editing of such works on natural history as have been published by Cassell and Co, and the present work, so far as its descriptive portion is concerned, can boast of being written by men so well known as Duncan, Dallas, and Murie, while the illustrations many of which are very beautiful, and the general style of the get-up of the volume may well be left to tell their own tale.

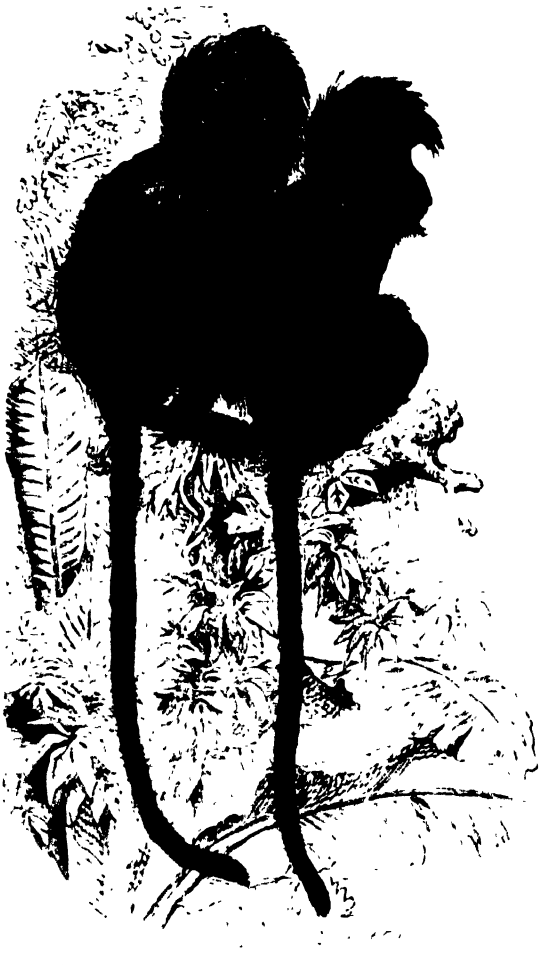

FIG. 1. The Negro Monkey (Semnopithecus maurus)

The work aims at being an encyclopædia of the Natural History of the Animal Kingdom, and this, which forms its first volume, contains an account of the apes and monkeys, by the Editor; of the lemurs, by Dr. Murie, and of the bats and insect-eating mammals, by Mr. Dallas. May we, in the interest of the success of the work, suggest, that in order to complete the publication of such a work, within a reasonable time, there ought to be different portions of it simultaneously published. Thus there would be nothing to hinder the volumes on fishes being published alongside of those of the mammals, and it would be decidedly well to publish those volumes that will treat of the sponges and corals long before this portion of the animal kingdom would in the ordinary course be reached; but we venture this only as a suggestion.

The Editor tells us that the volume before us is meant to explain the many interesting facts of the natural history of animals, and that every endeavour has been made to unite zoology with comparative anatomy; the aim is high and the idea is a good one, but the authors sometimes fail to come up to the standard they hold before them. It is perhaps not to be wondered at, for do not the very words of our English language seem to fight against the perfect accomplishment of such aims. Vertebra, says Dr. Duncan, is a Latin word, which means "a turning joint in the body," *or*, "a back bone." What idea will the English youth take away of this Latin word?

We regret a little to see the attempt to give each animal what we suppose we must call an English name, and we are tempted to ask, Which is it easier to say, *Troglodytes calvus* or *Nschiegombouve?* The former is the scientific name of a little-known ape; the latter is the name we are to make believe, as the young folk say, is English. It would have been better if both names had been equally conspicuous, then we could have taken our choice, and we can see no good reason for burying the scientific name in a foot-note.

As specimens of the style and illustrations, we have selected the following:—"The Negro Monkey (*Semnopithecus maurus*) (Fig. 1) is of an intensely black colour, except underneath, and at the root of the tail, where there is a grey tint. The paws are long, delicate, and silky, and become slightly grey on the head and back with old age. Like most black things it leads a troubled life, being chased and hunted, not, however, in the Javanese forests, and sometimes fifty or more individuals associate together. The Negro Monkeys make rude nests on trees, and are extremely timid, making off with great haste if they are disturbed. A long series of generations have been chased and killed by the natives of Java, and therefore the present Negro Monkeys are exceedingly shy, and bolt from the face of man at once. And yet, although thus timid and anxious to get out of the way, they have the reputation of being dangerous, and really unwittingly they may be so. On the approach of men they utter loud screams, and scamper off amongst the trees, helter-skelter. Now in doing this they break dead branches off, and sometimes a large fruit or nut comes tumbling down some score or two of feet. These are supposed to be thrown by the monkeys, but such is not the case. Having this bad character, the 'Negroes' are cudgelled with sticks, and killed in numbers very cruelly. Their pretty fur is much prized, and the chiefs of the country arrange the hunting parties, treating the monkeys really as beasts of the field. The skin is prepared by a simple process which the natives have learned from Europeans, and they conduct it with great skill. It affords a fur of a jet-black colour, covered with long silky hairs, which is used by the natives and Europeans there in ornamenting riding saddlery and in military decoration.

"When young they are of a brown or reddish tint, and thin grey tints appear preceding the intense black; they then eat buds and shoots and tender leaves, but in adult age they are fruit-consumers. When in captivity they are sullen and morose, and they will remain sulky for many months. This the natives know, and therefore they never try to tame them or to have them in their houses."

Another pretty illustration taken from the *Proceedings* of the London Zoological Society, is that of the Red-bellied Monkey (*Cercopithecus erythrogaster*), which is described as follows:—

"When living at the Zoological Gardens in the Regent's

---

[1] "Cassell's Natural History," edited by P. Martin Duncan, M.B. (Lond.), F.R.S. Vol i. Illustrated. (Cassell, Petter, and Galpin, London, Paris, and New York.)

Park, this pretty monkey, with a red chest and belly, and slim tail, was very timid, but it liked to be petted by the keeper, being somewhat distrustful of its more romping companions. It would take food out of his hand, and seemed pleased, and generally played with his fingers without attempting to bite. The canine teeth were very moderately grown (Fig. 2).

"This monkey inhabits Western Africa, and is at once known by the red belly and chest, the white beard and whiskers, and the black band across the forehead. It has, moreover, a yellow crown."

As a last illustration we select that of a most remarkable animal, the West African River Shrew (*Potamogale velox*, Fig. 3).

"This was originally described by its discoverer, M. du Chaillu, as a carnivore, under the name of *Cynogale velox*, but as its characters were very doubtful, the name *Potamogale* was suggested for it in case of its proving to belong to a distinct genus. The late Dr. Gray described it as a rodent under the name of *Mythomis*. Some years later Prof. Allman and Prof. Barboza du Bocage procured perfect specimens, and proved the animal to belong to the insectivora, the latter naturalist describing it under the new name of *Bayonia velox*. Thus within a few years it received no less than three different names.

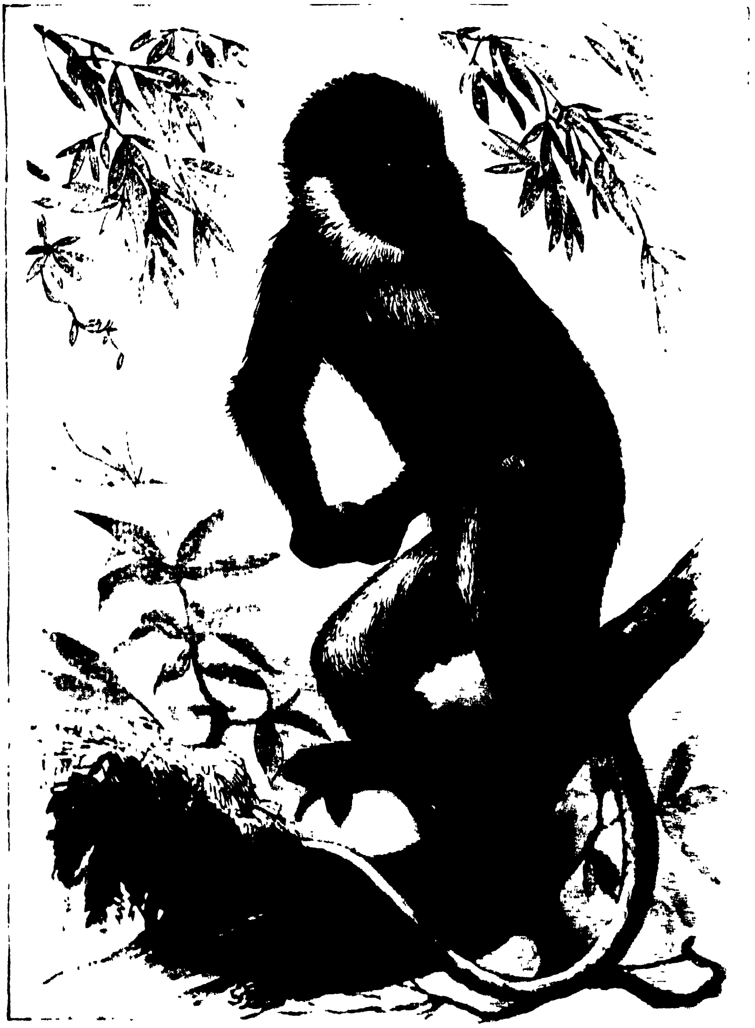

Fig. 2.—Red-bellied Monkey (*Cercopithecus erythrogaster*).

When the insectivorous nature of Du Chaillu's River Shrew was ascertained, it was found to be most nearly allied to the Centetidæ or Tanrecs, with special affinities to the West Indian Solenodens. It is, however, generally regarded as constituting a distinct family, characterised, among other things, by the less cylindrical skull, the absence of clavicles, the union of the two bones of the shank towards the extremity, the presence of anal glands, and the compressed form of the tail. The teeth, as in the true Tanrecs, are forty in number, but the molars differ considerably in form, as will be seen from the annexed figures.

This little beast, which has given rise to so much discussion among zoologists, and received so many names, is only a little larger than our common stoat, measuring about nine inches in length, exclusive of the powerful tail, which is of about the same length. In its appearance it very much reminds one of a miniature otter, from which, however, it differs considerably in the form of the head, which terminates in a broad flattened muzzle, having its sides furnished with a most luxuriant crop of stiff bristle-like whiskers. The hair of the upper part of the body and limbs is brown and soft, although rather coarse, and that of the lower surface yellowish; and the coat consists of two kinds of hairs, namely, an inner coat of very fine short silky hairs, through which longer hairs of a very peculiar structure project. These long hairs are very thin at the bulb, and increase very gradually in thickness for about one-third of their length, when they suddenly contract a little, and then expand into a flat lance-shaped blade, which terminates in a very fine point. This coarser part covers the whole body, the thick root of the tail, and the upper part of the limbs; the rest of the tail, the under side of the muzzle, and the upper surface of the feet are clothed with short, close hairs. The ears are of moderate size, the eyes very small, and the toes on all the feet, five in number, are armed with small sharp claws, and without webs, but the second and third toes on the hind feet are united as far as the end of the first phalanx.

The most remarkable peculiarity of the animal is its tail, which presents a most unusual development for an insectivorous mammal. Prof. Allman says:—"It is so thick at its base that the trunk seems uninterruptedly continued into it; but it soon becomes laterally compressed, and then grows gradually thinner and narrower towards the tip. . . . . Its lower edge is rounded, and its upper is continued into a membranous crest about one-eighth of an inch in height, and clothed with the same short, stiff, appressed hairs" as the rest of the tail.

This great development of the tail might of itself convince us that this organ is of great service to its owner, and such, from the account of the habits of the animal given by its discoverer, is evidently the case. M. du Chaillu says:—"This extraordinary animal (Fig. 3) is found in the mountains of the interior, or in the hilly country explored by me north and south of the equator. It is found along the water-courses of limpid and clear streams, where fish are abundant. It hides under rocks along these streams, lying in wait for fish. It swims through the water with a rapidity which astonished me; before the fish has time to move it is caught. On account of the rapidity of its movements I have given it the specific name of *Velox*. The animal returns to land with its prey almost as rapidly as it started from its place of concealment. The great motive power of the animal in the water seems to be in its tail."

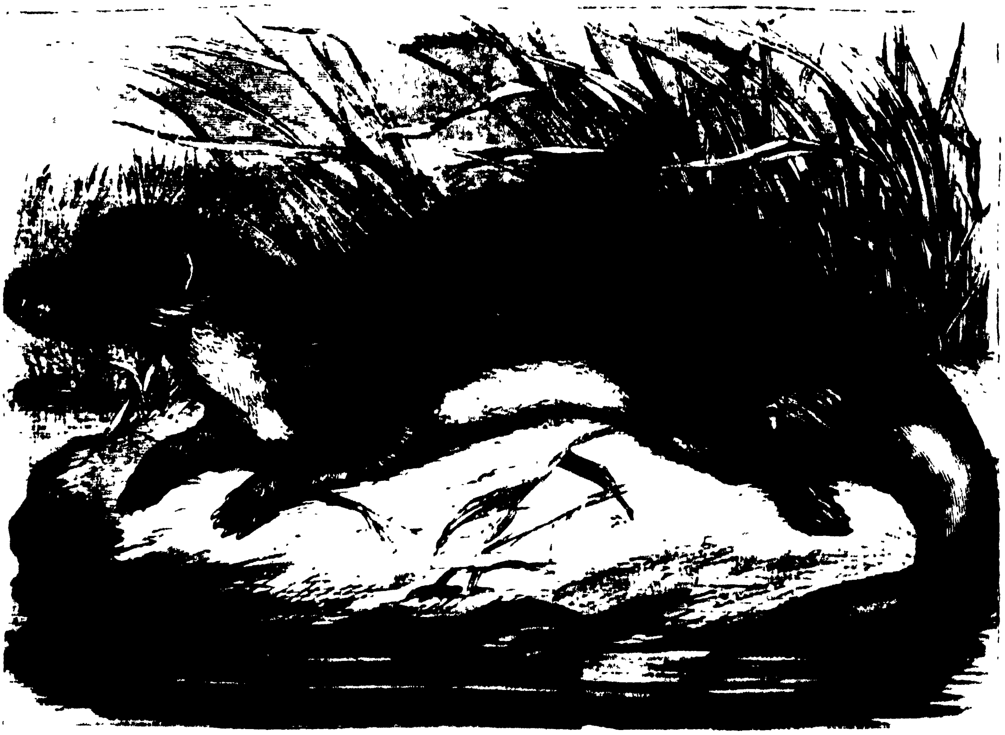

Fig. 3.—West African River Shrew (*Potamogale velox*).

So far as we have been able to read over this volume, we have found that great pains have been taken to record all the novel facts known about the animals here treated of. We perceive an account of the nest-building power of that most extraordinary Madagascar lemur, the Aye-Aye (*Cheiromys madagascarensis*) and the strange instances of mimicry about the bats, first noticed by Dr. Dobson, is to be found also noticed.

An index to each volume would be a very desirable addition.

NITRIFICATION

THE origin of salpetre is a subject which has vexed the minds of several generations of chemists. Nitrate of potassium, or salpetre, is found in nature as a white crust, appearing on certain rocks, old walls, and even upon the surface of the soil; from this mode of occurrence the name "salpetre" is doubtless derived. The largest natural source of salpetre is afforded by certain soils in India. Soil having a white film of salt on the surface is collected from the neighbourhood of house-drains and stables; the soil is washed with water, and the nitre crystallised from the solution. With this Indian salpetre England has been, till quite recently, almost exclusively supplied. The countries of Continental Europe, not having access to so considerable a natural source of nitre, have been obliged from early times to produce nitre for themselves. At first the earthen floors of cottages and stables were collected, washed, and nitrate of potassium obtained by treatment with wood-ashes and crystallisation; but the inconvenience of collecting such material, and its general poverty in nitre, soon led to attempts at producing salpetre by artificial means. To Glauber, a chemist of the seventeenth century, apparently belongs the credit of first preparing nitre artificially. The process as carried out in the present day is in outline as follows:—Soil, containing more or less of vegetable mould and carbonate of calcium, is mixed with a certain proportion of stable manure or other refuse animal matter, and disposed in small heaps, care being taken that the mass of soil and manure shall be sufficiently porous to ensure the free admission of air: these heaps are protected from rain, and are from time to time watered with stable sewage. At the end of two or three years the earth is sufficiently rich in nitre to be worth extracting. This tedious process for manufacturing nitre has, during the last few years, been superseded to a considerable extent by the treatment of Peruvian nitrate of sodium with chloride of potassium, by which nitrate of potassium and chloride of sodium are produced.

It is evident that the artificial nitre-beds just described, merely perform, on an exaggerated scale, an operation which occurs naturally in all ordinary soils. The chemical analysis of drainage waters has taught us that such waters are characteristically rich in nitrates, and that the amount of nitric acid present stands generally in close relation to the quantity of nitrogenous manure previously applied to the soil. The published analyses of the drainage waters from the experimental wheat-field at Rothamsted, show that ammonium salts applied as manure are rapidly converted into nitrates by the soil, the quantity of nitric acid in the drainage water being proportional to the amount of ammonium salt applied. The recent application of soil for the purification of sewage is another striking example of the same action. The sewage, as poured upon the soil, contains ammonia, and putrescible organic matter rich in nitrogen; the sewage which has filtered through a few feet of porous soil is found to contain nitrates, but only traces of organic nitrogen or ammonia.

What explanation can we give of this phenomenon of nitrification? It is clearly a process in which nitrogen is oxidised into nitric acid; but how is this oxidation brought about? The old chemists believed that a decaying organic body evolved more or less of its nitrogen in a free state, and that this nitrogen, while nascent, combined with the oxygen of the air to form nitric acid. This view has been held by some down to the present day. Hofmann, in his Exhibition Report of 1862, offers the same explanation, only substituting for free air the oxygen condensed on the surface of porous bodies. This theory has been extended by some to include the ordinary nitrogen of the atmosphere, so that on their view nitric acid may be formed in soil from the nitrogen and oxygen of the atmosphere, without the intervention of other nitrogenous matter. According to others the oxidation of gaseous nitrogen is brought about not by ordinary oxygen, but by ozone. Other chemists have inclined to the belief that nitrogen is never oxidised in the soil except when in the form of ammonia, and that the nitrogen of organic matter is always converted into ammonia as a preliminary to nitrification. According to some experiments, the ferric oxide, which gives a red colour to so many of our soils, is itself an oxidising agent, and capable of converting ammonia into nitric acid.

We need not, however, enumerate all the opinions that have been held on this confessedly obscure subject. Many of the experiments which were thought to support certain views, now appear, in the light of recent evidence, of little value. Before, however, discussing the new facts recently contributed to the subject, we may just indicate those points which have been most clearly established.

There is very little evidence for supposing that gaseous nitrogen is ever converted into nitric acid in the soil. Nitrous and nitric acid are indeed produced by electric discharges through the atmosphere, thus originating the small amount of nitrates brought to the soil by rain, but this appears to be the only reaction capable of producing nitric acid from the direct union of oxygen and nitrogen. According to Carius even ozone is quite incapable of oxidising gaseous nitrogen. Ammonia is, on the other hand, oxidised by ozone, nitric acid being formed; but that ozone is an agent in soil transformations is certainly unproved, and appears very improbable. There remains the action of ferric oxide, already referred to. This reaction deserves further study; it cannot, however, be considered as generally important, since nitrification certainly occurs with vigour in soils practically destitute of ferric oxide.

The researches of successive generations of chemists had thus failed to give any satisfactory explanation of the important phenomenon of nitrification. The subject has quite lately been attacked by Schloesing and Müntz from an entirely new point of view; their results, published in the early part of last year, plainly indicate that nitrification, instead of being brought about by purely chemical forces is, in fact, the work of a living organism. The evidence adduced in support of this new view is very simple. These chemists show that nitrification, however active, is immediately stopped by the vapour of chloroform, a substance which previous study has shown to suspend the action of yeast, and of all organised ferments. They also find that when nitrification has thus been suspended for many weeks, it can be restarted by the addition of a small quantity of a nitrifying body. In a second communication they further prove that the temperature of boiling water is sufficient to destroy all power of nitrification, and that soil which has been once heated to this point produces, in air free from germs, carbonic acid and ammonia, but no nitrates. If, however, this soil is moistened with water containing a little unheated soil, the production of nitric acid again commences.

This new theory of nitrification has been investigated at Rothamsted with results completely confirmatory of the views put forward by these French chemists. It was found that the vapour of bisulphide of carbon, and of chloroform, effectually prevented nitrification in a moist garden soil through which air was frequently aspirated, while without these vapours the soil produced nitrates in considerable quantity. A solution of chloride of ammonium containing a little tartaric acid, phosphate of potassium, and carbonate of calcium, was also completely nitrified in a few weeks by the addition of a small quantity of soil taken from the "fairy-ring" of a meadow. This solution, when nitrified, was successfully used as seed to produce nitrification in other similar solutions, which, without this addition, produced no nitric acid. It was further shown that light was prejudicial to nitrification; solutions kept in a dark cupboard producing nitric acid, while similar solutions standing in daylight produced none.

The evidence has thus become very strong that the nitrates in soil owe their origin to oxidation brought about by living organisms. That mycoderms, in their processes of life, may exert a powerful oxidising action upon organic matter, we have already learnt through the researches of Pasteur and others. The most familiar example is that of the acetic fermentation. Vinegar is produced by the oxidation of alcohol during the growth of a very simple organism, the *Mycoderma aceti*, without the growth of such an organism no vinegar is ever formed. It is by similar low organisms that fermentation of all kinds is brought about. Putrefaction has also been shown to be equally dependent on the presence of microscopic organisms, and except under the conditions suitable for their rapid development putrefaction will not take place. With this abundant evidence before us of the energetic decomposition of organic matter, brought about by what we may term microscopic fungi, we can hardly be astonished to find that the same agency is capable of oxidising the nitrogen of organic matter and of ammonia, and thus producing nitric acid.

The organisms which produce these wonderful changes consist of colourless cells; they are independent of daylight, for they derive their supply of carbon exclusively from organised matter, and from the decomposition of such matter they obtain the force necessary for life and growth. In these respects they differ entirely from green vegetation, in which sunlight is the source of all energy, and carbonic acid gas, decomposed by the aid of light, the material from which carbon is derived. The colourless and green organisms, however, equally require phosphoric acid, potash, and other ash constituents; and both appear to be capable of assimilating nitrogen in the form of ammonia.

Not only are these simple organisms independent of the aid of light, but light is, in some cases at least, actually fatal to their existence. This fact has quite recently been established by Downes and Blunt. They find that the *bacteria* present in an organic fluid may in many cases be entirely destroyed by exposure of the solution to daylight, and that even when this is not the case, their development is much retarded by such treatment. This observation is perfectly in accordance with the fact observed at Rothamsted, that nitrification did not proceed in solutions exposed to daylight. In the last communication of Schloesing and Müntz, it is stated that vegetable soil suspended in water by passing a stream of air through the mixture, undergoes nitrification both in light and darkness. No details of the experiment are given, but it seems probable that such a mixture would be more or less opaque, and the greater bulk of the material consequently at all times in partial darkness.

The microscopic organism producing nitrification has probably distinctive characters, and might be isolated by cultivation under conditions specially suitable to its growth, but more or less unfavourable to the life of other associated germs. Pasteur has pursued this method with success in the case of beer yeast, and has shown that with the pure yeast thus obtained an unchangeable beer may be manufactured, the organisms producing secondary changes having been excluded. The subject of nitrification has clearly reached a stage which demands the aid of the vegetable physiologist.

R. WARINGTON

FOSSIL HUNTING AT BOURNEMOUTH

I HAVE recently deposited in the South Kensington Museum some unusually large specimens of fossil plant remains from Bournemouth and Studland. The matrix in which these are imbedded is friable, and the remains, in most cases, are extremely difficult to extract, so that a brief account of the process employed may be of use to would-be collectors. The largest specimen, part of the frond of a feather-palm, measures 4 ft. by 3 ft., and as this presented the greatest difficulties, I will more particularly describe the work which its preservation involved.

In digging last autumn at Bournemouth in a bed of dark clay about 60 feet above the sea-level, and about the same distance from the top of the cliff, we came across a well-preserved fragment of this specimen consisting of a portion of the stem with the bases of pinnæ attached. We included a younger athletic brother, a coast-guardsman whom I have long employed, as well as myself, and occasional other assistance. The tools we used were pick-axes, crow-bar, and spades. The place was a slightly projecting ledge, none too solid, with a steep cliff above and below. So soon as the fragment mentioned was brought to light by a stroke of the pick digging was stopped, and a careful examination was made by the aid of our knives to see in which direction the frond trended. Finding, fortunately, that the direction was towards the mass of the cliff, we determined to use our endeavours to extract it in as perfect a condition as might be. We therefore, at about mid-day, commenced to dig away the superincumbent mass until a slab was bared at least twice the size of that ultimately required, when we proceeded to clear down and lay bare the specimen. Loose sand blowing up in clouds, however, settled upon it and threatened to adhere so firmly to the wet clay that it was feared it might be found impossible to remove it, whilst the drying action of the wind caused it to crack and peel, notwithstanding all our efforts to keep it covered with damp paper and linen. It was then determined to remove the slab without exposing the leaf, leaving that operation until it was safely housed at home, and we therefore commenced the laborious operation of undermining this great slab and removing it in such pieces as from time to time broke away by their own weight from the main mass. For five hours these pieces kept breaking away in blocks of about one foot in thickness, and as much in weight as two or three of us could lift. At dusk our task was not more than two-thirds completed, but as wet was expected, it was determined to extract the whole that night if possible. Perhaps the most toilsome part of the work was carrying the pieces up the sixty feet of cliff. A hand-barrow having been improvised, it required our united efforts to convey each piece to the path above, and this was really hard work, and in addition I had great anxiety throughout lest the edges should be rubbed. Notwithstanding all our trouble we had the mortification of seeing our large lumps repeatedly break and subdivide. The work went on until about 9 P.M., when we found it impossible to continue, and therefore carefully covered up the remains of the slab, the vicinity of a populous town rendering this precaution necessary. The next day the whole of the pieces were removed in a cart from the coast-guards station to an out-house in our occupation. When they arrived there the prospect was far from hopeful. We had apparently but a truckful of lumps of black wet clay, a foot or more in thickness, and varying in diameter from a few inches to two or three feet, the majority without trace of the fossil upon them, or any marks or indication of how they were to be fitted together. Experience among these fossils has taught me not easily to despair, and I knew, moreover, from the care that had been taken, that the edges could not be much abraded, nor could any considerable pieces be missing. Our lodging contained a new and comparatively well-lit cellar, to which all was removed. A table was next made, six feet long and four feet wide, and portions of three days occupied in ascertaining how the pieces could be fitted together.

Two days were then lost in fastening the smaller pieces together into larger slabs, but it was found that these larger pieces would not come together properly in the box, their relative thickness, &c., being different. They were next reduced in thickness to about three inches and transferred to the box in which they now are, and fitted together as accurately as possible and fixed by glue and plaster of Paris, ¾ cwt. of the latter being used.

A great disappointment now awaited us. From standing and kneeling upon the slab whilst engaged in digging it out, the upper surface of the leaf was kneaded into the under surface, and would not part for weeks afterwards, until quite dry, and then in very small fragments only.

Another difficulty was that two other fronds were found at lower levels traversing the one we were endeavouring to save, and in some places these had been cleaned out before the mistake was discovered. The base of the frond, it will be seen, has been abandoned altogether, and not more than two-thirds is now preserved. The next thing was to get it to London safely, and the railway officials were cautioned as to the care required and the necessity of keeping it flat and right side up, and the case was insured. Even while I was in the office insuring it a stupid porter tilted it over face downwards to my great grief, as I had little hope that the plaster would hold with such a weight if the case were subjected to this treatment on the way. I was relieved in my mind a few days later by its safe arrival at home. From this time patience alone was required, and by Christmas, with the aid of Mr. De Wilde, the whole leaf was uncovered and varnished and all the cracks filled in with modelling clay.

The other specimens were obtained in more or less the same way. The small feather palm was extracted whole with the assistance of Mr. Henry Keeping, of the Woodwardian Museum, but fell to pieces on the shutter to which it was transferred for carriage, and great care was needed to put them together as they now are. The Studland fan-palm being rotted by exposure on the face of the cliff and being penetrated everywhere by rootlets, fell into a hundred pieces, and only the centre of the leaf could be pieced together the rest being pulverised in its journey from Studland to Wareham.

J. S. GARDNER

FATHER SECCHI

SOME little time ago we announced the serious illness of Father Secchi, the well-known astronomer and Director of the Observatory of the Collegio Romano, at Rome; last week we chronicled his death, which occurred on the 26th ult. The illness which has thus terminated fatally, has cut him off, we may say, in the prime of his life, and in the midst of his work; for, till he was taken ill, there were no signs of any diminution of his energy, and he was only fifty-nine years of age when he died.

Secchi was born at Reggio, on June 29, 1818. Educated and trained from early youth as a Jesuit, we hear of him first in connection with science as Professor of Physics at Georgetown College, near Washington, and next as holding the same chair in the Roman College at Rome. It was in connection with the observatory attached to this institution that almost all Secchi's work for the last thirty years has been done. While the Roman College was in papal hands no funds were spared to make the observatory as complete as possible. Secchi had instruments and assistants in abundance, and his various series of "Memoirs" testify to his industry in many fields, while his position gave him great facilities for giving the widest publicity to his work. What he lacked in originality he made up in assiduity, and hence, although he has left no great life work on any one subject behind him, there is, we think, hardly any question which has turned up touching observations in astronomy, magnetism or meteorology on which a multitude of papers have not been written by his busy pen. Many of these papers are very admirable and show great penetration and power of generalisation as well as a wide grasp of many subjects.

Secchi's great interest in solar physics was doubtless aroused, when in America, by assisting Prof. Henry in making the first experiments on the heat radiated by different portions of the sun's disc by means of the thermo-electric pile. His interest in spectroscopy dates from Janssen's visit to Rome, when on his scientific mission to Italy and Greece. In both these branches of work Secchi has been an ardent observer and voluminous writer. He photographed the eclipse of 1860 in Spain, and observed the one of 1870 in Sicily. In 1867 he was in Paris exhibiting his universal meteorograph in the exhibition of that year, and giving lectures, some of which eventually formed the basis of his book on the Sun, a second edition of which appeared last year. Besides this book on the Sun, he has written others on the Unity of the Physical Forces, and on the Stars, the latter of which has not yet appeared.

When the States of the Church became Italian the Roman College was among the institutions which were turned to other uses by the new government. This now contains two most interesting museums, one of educational apparatus chiefly for primary instruction, and another for antiquities. The new Government, however, were extremely anxious not to interfere with Secchi's scientific labours and offered him the Chair of Astronomy in the new Roman University, at the same time granting ample funds for the prosecution of his inquiries. This Secchi accepted, but soon found his occupation gone, as he was commanded by the chief of the Jesuits to resign it, which he did. It is doubtful whether any *modus vivendi* would have been found if the king, whose foster-brother he was, had not stepped in between the Ministry and the Vatican, and suggested a compromise which would have left Secchi to continue his work under most favourable conditions, if the Jesuits had not again stepped in.

One of the most recent results of Secchi's energy has been the foundation of the Società degli Spettroscopisti Italiani, a society specially constituted for recording daily spectroscopic observations of the sun, chiefly at the various observatories of Italy.

There is no doubt that in the death of Father Secchi observational astronomy has sustained a great loss. His industry and skill were largely rewarded during his lifetime. In 1867 he received the great French prize of 100,000 francs. He was a member of most scientific societies, including our own Royal Society, and it must not be forgotten that if there may have been traits of Secchi's character open to criticism, the exigencies of his post, rather than the inclinations of the man, may have been to blame.

NOTES

THE French expedition for the observation of the approaching transit of Mercury consists of M. C. André and M. Angot, who formed likewise part of the expedition to New Caledonia, on the occasion of the transit of Venus. Ogden, in the State of Utah, has been selected by the French Institute as the most favourable locality for the observation, and the expedition is already under way to its destination. A Parisian millionaire, well known for his generosity towards scientific objects, has contributed 30,000 francs to defray the expenses of the observation.

WE regret to learn of the dangerous illness of the well-known mineralogist, M. Delafosse Gabriel, professor at the Muséum d'Histoire Naturelle of Paris. He is now in his eighty third year, and has been for twenty years a member of the French Academy of Sciences.

THE Royal Academy of Sciences at Berlin has elected the well-known Prof. Noeldecke, of Strassburg, a corresponding member.

ARRANGEMENTS are being made at Paris for the erection of a fitting monument to the late Claude Bernard. The initiative has been made by the *Société de Biologie*, of which Bernard was one of the founders, and over the meetings of which he has presided during the past eleven years. The committee appointed for the purpose contains prominent names from all the leading scientific institutions of Paris.

THE death is announced of Mr. Joseph Bonomi, the distinguished Egyptologist, which occurred at Wimbledon Park on Sunday last, at the age of eighty-two. For the last sixteen years Mr. Bonomi has acted as Curator of the Soane Museum in Lincoln's Inn Fields. Mr. Bonomi went out to Egypt as early as 1824, and spent eight years on the banks of the Nile, drawing and studying the ancient temples and their wonderful sculptures. During this time he had adopted the Arab costume and mode of living, and by this means he was able to go on in the prosecution of his studies with his then limited resources. He returned to England, where he remained till the visit of Lepsius in 1842, when he went out as artist in that expedition, which resulted in a large folio work of about twenty vols., published under the auspices of the King of Prussia. The Egyptian Court at the Crystal Palace was erected from Mr. Bonomi's designs and under his superintendence. He was also employed in the British Museum in arranging the department of Egyptian antiquities. Mr. Bonomi has rendered great service, not only by his illustrations, but also by his writings on subjects connected with the various countries in the east which he visited. These will be found in the *Transactions* of the Royal Society of Literature, Syro-Egyptian Society, British Association, &c. Mr. Bonomi leaves a great mass of notes and sketches of hieroglyphics which may yet be of great value to Egyptology.

AT the General Monthly Meeting of the Royal Institution on Monday, the special thanks of the members were given to Dr. Warren De la Rue, D.C.L., for his donation of 50*l.* for the benefit of the Chemical Laboratory.

WE would remind our readers that subscriptions are still being received for the Simon Testimonial Fund. A marble [illegible] is the form of testimonial that has been decided on, and a [illegible]ll copy of this will be presented to each subscriber of two guineas and upwards. No testimonial was ever better deserved. Subscriptions may be sent to Robarts, Lubbock, and Co., Lombard Street, to the Hon. Secretary, 1, Adam Street, Adelphi, or to the Treasurer, General Register Office, Somerset House.

THE Atlas of Colorado, soon to be issued by the U. S. Geological Survey of the Territories, under Prof. F. V. Hayden, embodies the results of the geological and geographical work of the survey during the years from 1873 to 1876 inclusive. This Atlas will contain the following maps:—1. A general drainage map of Colorado on a scale of twelve miles to the inch. 2. An economic map of the same region, having as its basis the above-mentioned drainage map. This map will indicate the areas of arable, pasture, timber, coal, mineral, and desert land in as great detail as possible on the scale. 3. A general geological map, on which the areas covered by the principal formations will be shown. The drainage map will form the basis for this also. 4. A map showing the scheme of the primary triangulation in the state. Scale twelve miles to the inch. 5. Six topographical sheets showing the same area as that covered by the general drainage map, but in much more detail. The scale of these sheets is four miles to an inch. The relief of the country is indicated by contour lines, at vertical intervals of 200 feet. The area covered by each of these sheets is 11,500 square miles. 6. Six geological sheets, of which the bases are the six topographical sheets just mentioned. On these the detailed geology is expressed by colours. With the appearance of this map, Colorado will be better known, topographically and geologically, than any other State.

ONE of the leading publishing houses of Paris is making arrangements for the speedy appearance of an enormous work, "Études sur l'Exposition de 1878," under the direction of M. E. Lacroix. This work is intended to be a complete record of the progress made in all the arts up to the present date, and its thoroughness and value have been assured by the promised co-operation of a large number of leading authorities. The French Ministers of Public Works, of Commerce, and of Agriculture have already promised all necessary assistance on the part of the Government, so that the undertaking will start under the most favourable auspices.

DR. SCHLIEMANN intends to resume his excavations at Hissarlik as soon as the country is at all safe to live in.

THE Society of Arts prize of 10*l.* for the best set of blowpipe apparatus that could be sold retail for one guinea, has been awarded to Messrs. Letcher, of Camborne and St. Day, Cornwall. A second prize, consisting of a bronze medal, has been awarded to Herr Osterland, of Freiberg.

THE establishing of a branch of the U.S. National Observatory, to be placed at some elevated point in the West, has lately been agitated, and much is expected as the result of its completion.

ON July 16 an International Exhibition of the Paper Trade will be opened at Berlin and will last until August 31. The programme of the exhibition is already finally settled, and the objects exhibited will be divided into eight different groups, viz.: 1. Raw materials and articles used for making paper, pasteboard, &c. 2. Machines and tools used for making and working paper. 3. Paper and boards of all descriptions. 4. Paper, as far as it is employed for printing, paper-hangings, &c. 5. Articles made of paper or *papier-mâché*. 6. Paper as used for technical or building purposes. 7. Writing and drawing materials. 8. Objects, books, &c., relating to the history and literature of paper. A number of prizes will be awarded for the best contributions.

THE system of agricultural weather-warnings in France, carried on under the direction of the Paris Observatory, continues to be rapidly developed and extended to all parts of the country. The warnings are now sent to 1,432 communes spread over all the departments of France except that of Lozère.

A NOVEL and valuable application of electricity, designed to prevent the possibility of collisions on railways, is now the subject of experiment in the Marseilles station. It consists of an electric mirror, in which all the movements on a line 100 kilometres in length are brought vividly before the eye, and enables the station-masters to follow exactly the progress of every train. By this means it is hoped that all accidents resulting from delays or too rapid runs can be entirely avoided, and arrangements are being made for the general introduction into the stations of the new invention.

A VIENNA mechanician has recently succeeded, after many fruitless trials, in constructing a sewing machine which does not require the person working at it to submit to the unpleasant and unhealthy necessity of constant bodily exertion, viz., setting the machine in motion by the foot. Since, for pecuniary reasons, the application of electricity, steam, or water power was impossible, the inventor of the new machine was restricted to gravitation or elasticity, and he, preferring the latter force, has contrived to make springs strong enough to keep an ordinary sized machine in motion for hours. A system of cog-wheels is arranged underneath the surface of the table upon which the machine is fixed, and by a handle at the side the spring is wound up with the greatest facility. The velocity at which the machine works is entirely at the option of the person using it, and can be regulated *ad libitum*, and in the simplest manner.

OPPORTUNITY has been taken recently by MM. Raehlmann and Witkowski to observe the eye-motions of persons asleep, new-born children, blind persons, and also in circumstances presenting some resemblance to sleep, viz., drowsiness, intoxication, chloroformic sleep, and epileptic attacks, these cases having in common the failure of the will or the power for binocular vision. In every instance strongly uncoordinated movements were observed. The result is regarded as opposed to the idea of a mechanism possessed at birth for producing regular motions of the eyes, and as agreeing with Helmholtz's view:—"Though each eye has a quite independent muscular mechanism . . . . we have only learned to perform those movements which are necessary for seeing a real point distinctly and simply." Where this interest is not yet present, as in newly-born infants, or where it disappears, as in the case of the blind, and in the sleeping, there occur divergences from the law of adaptation.

THE German Verein zur Beförderung des Gewerbfleisses has offered extensive prizes for the invention of substitutes for caoutchouc and gutta-percha.

NEWS from South America states that powerful waterspouts were recently experienced at Callao, doing considerable damage in the town and its environs. On January 27 Callao suffered again severely from a repetition of the phenomenon known as the "tidal wave," from which so much damage was done in May last. Much destruction of buildings has resulted. On January 23 a strong earthquake, lasting thirty seconds, was felt at Iquique and Arica; shocks recurred on the 24th and 25th. On December 31 a violent thunderstorm visited Lima, accompanied by torrents of rain. The latter phenomenon is of extreme rarity in that neighbourhood, and during the present century has occurred there only once, viz., in the year 1804.

THE *Moniteur Vinicole* announces the surprising fact that the wine-production of France has not been diminished of late years, in spite of the devastations of the pernicious insect, phylloxera. During the five years, 1862 to 1867 (before the vast spreading of the plague), the annual production averaged 54,747,405 hectolitres. During the five following years (1867 to 1872) it rose to 56,527,129 hectolitres. After 1872, since when the phylloxera invasion began to reach its maximum height, the average annual production has not sunk below 56,000,000 hectolitres. The total of last year's produce amounts to 56,405,363 hectolitres, as against 41,846,748 in 1876.

THE statistics of the German Imperial Telegraph Office for 1877 have just been published. When the Telegraph Office was united with the Post Office there were 1,688 telegraph stations in Germany. At the end of 1877 this number had risen to 3,287.

THOSE desirous of sending objects of natural history from Guatemala (Central America) to the forthcoming Paris Exhibition are requested to communicate with M. A. Boucard, of 55, Great Russell Street, W.C., until the 20th inst. After that date all communications should be sent to the following address:— Legacion de Guatemala, 3, Rue de Copenhague, Paris.

THE experiments on the practical value of the telephone, carried out by the German postal department, show that it is not adapted to supersede the telegraph on lines which are constantly in use. For local purposes and lines less frequently used it will, however, be introduced on a large scale, a large pecuniary saving being effected by the ease in obtaining officials who have not had to master the difficulties of telegraphy. The department has also introduced an apparatus for calling the official at the station to which a message is to be sent, so that an electric battery is now unnecessary for the purpose of summoning attention.

AUSTRALIAN colonists have noticed some strange peculiarities in bees imported from Europe, which, however unpleasant they may be to the agriculturist, are yet of the highest interest to naturalists. It appears that our European bees retain their industrious habits only for the first one or two years, when imported into Australia. While during that period they keep their hives in good order and yield a fair quantity of honey, they gradually cease to collect honey after that time, and soon become entirely barren.

MR. MURRAY has published in a neat little volume, Virchow's address at the German Association last autumn, on the Freedom of Science in the Modern State. We are glad this has been done, as the address is one well worthy the attention of men of science. It was our sense of its importance that induced us some months ago to publish in our columns a verbatim translation of the address, as well as translations of the addresses of Haeckel and Nägeli, on which Virchow's address is to a large extent a criticism and reply.

THE master of the *D. M'B. Park* (British barque), which arrived at West Cowes (I. W.), March 3, from Batavia, reports as follows:—January 29, at 7 A.M., in lat. 4.20 N., long. 21.45 W., saw several submarine volcanoes throwing large columns of water about 100 feet into the air, while the sea was in great commotion, as it is when there is a very strong under-current, the weather at the time being very cloudy, with rain, and nearly calm. The sound was like distant thunder.

VARIOUS theories have been offered of the sense of temperature. In a recent one by M. Hering it is represented that when at a given part of the skin we feel neither heat nor cold, the feeling of temperature at that part is, so to say, at *zero*. The main points of the theory are these: The feeling of temperature depends on the height, for the time being, of the temperature proper (*eigen Temperatur*) of the nervous apparatus of the skin, not on the rise or fall of this temperature (Weber) nor on the intensity and direction of the heat current (Vierordt). Every temperature of the nervous apparatus above the zero point is felt as heat, every one below as cold. The distinctness of the sensation of heat or cold increases with the distance of the temperature proper for the time being, from the zero temperature. The zero temperature is variable within certain limits. Every temperature of the nervous apparatus, felt as warm, causes a displacement of the zero point of the scale of sensation upwards, and every temperature felt as cold causes a displacement downwards. These ideas are developed by M. Hering, in a recent paper to the Vienna Academy.

M. LENGLEN, a physician of Arras, has recently described a remarkable perpetuation of physical traits. A certain M. Gamelon, in the last century, was sex-digital, having two thumbs on each hand and two great toes on each foot. The peculiarity was not noticeable in his son, but in each of the three subsequent generations it has been strongly marked, some of the children at present showing the malformation as distinctly as their great-great-grandfather. M. de Quatrefages has noticed, a few months since, a similar case in the animal kingdom. A six-toed cock having transmitted this peculiarity to his descendants, it has spread to such a degree, that in the district where it occurred the ordinary five-toed variety is no more to be met with.

LIME, strontian, and baryta have recently been obtained in the crystalline state by Dr. Brugelmann, of Dusseldorf (*Ann. der Phys.*, No. 11), by heating their nitrate salts till complete decomposition takes place. In this way are obtained the three oxides in (chiefly) microscopical crystals of the regular system, and exclusively hexahedra. While, however, in the case of strontian and baryta, this interesting fact and new example of isomorphism is recognisable only with aid of the microscope, the lime can be easily obtained in large crystals, observable with the naked eye. Dr. Brugelmann describes his method fully, as also the form and properties of the three crystallised alkaline earths.

IT was pointed out some time ago by M. Herwig, that when strong induction shocks are sent through liquids they do not pass conformably to Ohm's law; there is at first a retardation of the electricities in the electrodes, and the equilibration which at length occurs is somewhat like a discharge, as in the case of a large condenser. The phenomenon has of late been more fully studied by M. Herwig, who describes various interesting experiments with reference to it in the *Annalen der Physik*, No. 12.

M. GASTON PLANTÉ describes at length in the last number of the *Annales de Chimie et Physique*, his newly-discovered method for the engraving of glass, a process which promises to be of widely-extended application. His attention was first directed to this line of investigation by the observation that glass moistened with a solution of ordinary salt was strongly attacked by currents from secondary piles. As perfected, his process consists in immersing a plate of glass in a shallow basin containing a concentrated solution of potassic nitrate. It is encircled by a platinum wire also covered by the liquid, and connected with the pole of a secondary battery of fifty elements. The other pole consisting likewise of platinum wire covered with an insulator is held in the hand and applied to those parts of the glass where it is designed to engrave. A flash of light is produced by every contact with the electrode, and a mark accompanies each luminous appearance. The depth and fineness of the lines described depend directly on the rapidity with which the electrode is moved, and the fineness of its point.

THE Deutsche Gesellschaft fur öffentliche Gesundheitspflege has appointed a commission to co-operate with the government meteorological stations, in endeavouring to obtain the daily publication of the weather observations with probabilities for the following twenty-four hours, according to the American system.

THE additions to the Zoological Society's Gardens during the past week include two Brown Coatis (*Nasua nasua*) from South America, presented by the Hon. C. H. Wynn; a Palm Squirrel (*Sciurus palmarum*) from India, presented by Miss Barclay; two Rock Sparrows (*Petronia stulta*), South European, presented by Mr. D'Arcy Thompson; an Ocelot (*Felis pardalis*), a Red and Yellow Maccaw (*Ara chloroptera*), a Yellow Snake (*Chilobothrus inornatus*) from South America, two Black-capped Bitterns (*Butorides atricapilla*) from Africa, a Four-lined Snake (*Coluber quadrilineatus*) from Egypt, deposited; a Yellow-cheeked Amazon (*Chrysotis autumnalis*) from Honduras, purchased; a Red Kangaroo (*Macropus rufus*), an Indian Muntjac (*Cervulus muntjac*), born in the Gardens.

EXTENT AND PRINCIPAL ZONE OF THE AURORA BOREALIS

IN the *Wochenschrift für Astronomie*, Herr H. Fritz has recently compared his "Catalogue of Polar Lights," which contains notes of all auroræ which have been observed since 1846, with a publication of Herr A. Moberg, who gives an account of all auroræ observed in Finland during the years 1846 to 1855—some 1,100 in number. The comparison yields some interesting results which are not without importance for the theory of the phenomenon.

It appears that out of 2,035 days of the months from August to April, upon which auroræ were seen and which are entered in Herr Fritz's Catalogue, no less than 1,107 days were auroral days in Finland. Of these 1,107 auroræ 794 were simultaneously visible both in America and Europe, 101 only in Europe, while the remaining 212 were only seen in Finland. During the same period (1846 to 1855) 628 auroræ were seen in Europe or America which were not visible in Finland. All these figures of course refer only to the months from August to April, since during the summer months no phenomena of the kind can be observed in Finland on account of the brightness of the nights. As Herr Moberg's observations were collected from 128 different stations in Finland, we must conclude that only a very small number of auroræ remained unnoticed. We thus arrive at the conclusion that a great number of auroræ cannot have a very widely extended sphere, or that the causes of these phenomena must often be of a very local character (this is confirmed by several observations at high latitudes), while with another part of the phenomena the extension of their sphere or district of simultaneous visibility must be very considerable. The number of auroræ which were seen in Finland only—at least for which up to the present no data of observation elsewhere have been received—is very small (212, or only 19 per cent. of the total number seen in Finland). As the frequency of the phenomena increases—at the time of the maximum—the number of simultaneous observations in Finland and America rises, while the numbers of auroræ seen in Finland and Europe only, or of those exclusively seen in Finland, decrease. This agrees perfectly with the well-known law that with the increase of frequency of polar lights their intensity and sphere of visibility increase also. If we carefully take into account the less prominent phenomena the above proportions would be slightly modified, but most probably they would never prove that on any day when an aurora was visible only in a small district in Europe, another one was simultaneously seen in America. Thus the comparison made by Herr Fritz contradicts Renou's view that the phenomena in America and Europe change periodically.

Of 2,878 days on which auroræ were observed in America during 1826 to 1855, there are 1,065 on which auroræ were also seen in Europe, so that at least every third observation was simultaneous in both parts of the world. For the years during which more exact observations were made, viz., from 1846 to 1855, and again from 1868 to 1872, we find that during the former period out of 1,691 auroras 657 were simultaneously observed both in America and Europe; and during the latter period out of 715 no less than 397, or far more than half the number. If the catalogues were more perfect the number of simultaneous observations would, beyond doubt, be found to be still greater. Some observations made in Scotland give similar results to those dating from Finland, but their publication must at present be delayed, since the American data for comparison are still wanting.

The local occurrence of auroræ does not speak favourably for the hypothesis which places the phenomenon among the cosmical ones. Some ten years ago Herr Fritz published his views with regard to the geographical distribution of auroræ, and constructed a system of lines which he termed Isochasms—*i.e.*, curves of equal frequency of auroræ. The outlines of this system were as follow:—The zone of greatest frequency and intensity of auroræ began near Barrow point (72° north latitude) on the northern coast of America; thence it passed across the great Bear Lake towards Hudson's Bay, crossing the latter at 60° N. lat., passing over Nain, on the coast of Labrador, keeping south of Cape Farewell; its further course was between Iceland and the Far Oer to the vicinity of the North Cape in Norway, and thence into the Arctic Sea. According to the observations then in possession of Herr Fritz, the line passed round Novaya Zemlya and Cape Tsheljuskin, approached the north coast of Asia, in the eastern part of Siberia, in the longitude of Nischni Kolymsk, and thence returned to Barrow Point.

Now after ten years, in spite of the vastly accumulated material of careful observations, there appears no necessity to change Herr Fritz's system of curves in any essential detail; indeed certain parts of the same, which were at first only based on probability and supposition, the part of the principal zone between the north of Norway and Nishni Kolymsk as an instance, we now know with perfect certainty to be correct. Nearly identical, perhaps entirely so, with the line of greatest frequency is the line which marks the limit of visibility of auroræ towards the pole or the equator; since to the north of the line in question the auroræ are only seen in the direction of the equator.

PARIS ACADEMY PRIZES FOR 1878

I. EXTRAORDINARY PRIZES.—Grand prizes in the Mathematical Science.—1. The application of the theory of elliptic transcendants or abelians to the study of algebraic curves. 2. It is known that the great axis of the orbit which a planet describes round the sun is not affected by any secular inequality of the order of the two first powers of the disturbing masses. Examine if there exists in the value of this great axis secular inequalities of the order of the cube of the masses, and, in the case where these inequalities are not rigorously destroyed, give the means of calculating their sum, at least approximately. The prize is a medal of the value of 3,000 francs. 3. Study of the elasticity of crystallised bodies, from the double point of view of experiment and theory. Prize the same as No. 2.

Grand prizes in the Physical Sciences.—Study of the mode of distribution of marine animals on the littoral of France. A medal of 3,000 francs value.

An extraordinary prize of 6,000 francs will be awarded as a recompense for any progress calculated to increase the efficacy of the French naval forces.

II. MECHANICS.—1. The Poncelet prize of a medal of 2,000 francs value, and a complete copy of Poncelet's works, are awarded to the work contributing most to the progress of the mathematical sciences, pure or applied, published in the course of the ten years preceding the judgment of the Academy. 2. A Montyon prize, a medal of 427 francs value, will be awarded to any one who, in the judgment of the Academy, is most deserving, by inventing or improving instruments useful to the progress of agriculture, the mechanical arts, or the sciences. 3. The Plumey prize, a medal of 2,500 francs value, awarded to the author of an improvement of steam-engines, or of any other invention contributing most to the progress of steam navigation. 4. The Bordin prize, a medal of 3,000 francs value, will be awarded for a satisfactory solution of the following problem:—To find the means of destroying, or at least seriously diminishing, the annoyance and the dangers arising from the products of combustion issuing from the chimneys of locomotive engines, steamships, and manufactories near towns.

III. ASTRONOMY.—1. The Lalande prize, a medal of 542 francs value, will be awarded to the person who shall have made the most interesting observation, or to the memoir or the work most contributing to the progress of astronomy. 2. The Damoiseau prize, a medal of 5,000 francs value, will be awarded (in 1879) for a solution of the following question:—Revise the theory of the satellites of Jupiter; discuss the observations, and deduce from them the constants they contain, and particularly that which furnishes a direct determination of the rate of light; finally, construct special tables for each satellite. 3. The Valz prize, the proceeds of a sum of 10,000 francs, will be awarded for the most interesting astronomical observation made during the year.

IV. PHYSICS.—The Bordin prize, a medal of 3,000 francs value, will be awarded for a solution to the following:—Various formulæ have been proposed to replace Ampère's law on the action of the elements of currents; discuss these various formulæ and the reasons which may be alleged for giving the preference to one of them. 2. Three Lacaize prizes of 10,000 francs each will be awarded (in 1879) to the works or memoirs which have contributed most to the progress of physiology, physics, or chemistry.

V. CHEMISTRY.—The Jecker prize of 10,000 francs will be awarded to the researches which the Academy judges best calculated to accelerate the progress of organic chemistry.

VI. BOTANY.—1. The Barbier prize of 2,000 francs will be awarded to anyone who makes a valuable discovery in surgery, medicine, pharmacy, or botany, in connection with the art of healing. 2. The Alhumbert prize, a medal of 2,500 francs value; the subject of this prize is a study of the mode of nutrition of fungi. 3. The Desmazières prize of 1,600 francs will be awarded to the best or most useful writing on the whole or part of cryptogamy published during the year. 4. The Shore prize of 200 francs will be awarded to the author of the best memoir on the cellular cryptogams of Europe, or on the habits or anatomy of a European species of insect. 5. The Bordin prize of 3,000 francs has for its subject the following:—Explain by direct observations and by experiments the influence which the medium exercises on the structure of plant organs (roots, stem, leaves); study the variations which terrestrial plants undergo when raised in water and those which aquatic plants undergo when forced to live in air. Explain by direct experiments the special forms of several species of maritime flora.

In medicine and surgery the Bréant prize of 100,000 francs for a cure for Asiatic cholera still stands.

One or more Montyon prizes are awarded to works or discoveries which show the means of rendering an art or occupation less insalubrious.

The competition closes on June 1 each year. Works sent in are not returned, and the conditions as to the use of mottoes, concealment of names, &c., usual to such competitions are required.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

SCIENCE IN SCHOOLS.—Sir John Lubbock has given notice on an early day to move in the House of Commons that it would be desirable to modify the Code of Education by adding elementary natural science to the subjects mentioned in Article 10, c. 1.

BRESLAU.—The number in attendance at the University during the present winter is 1,253, divided as follows among the faculties:—Theological, 101; legal, 432; medical, 168; philosophical, 552. The University possesses one of the most valuable libraries in Germany, numbering over 400,000 volumes and several thousand valuable manuscripts.

BERN AND ZURICH.—The former University is attended at present by 410 students, the latter by 318. Each University includes in its list nineteen female students, most of whom are preparing for medical examinations.

LIBRARIES OF GERMAN AND AUSTRIAN UNIVERSITIES.—Most of the German States place annually considerable sums at the disposal of the University libraries. Bavaria gives her universities each 1,000*l.* for this purpose; Saxony grants 1,200*l.* to Leipzig; while in Prussia the sums vary from 600*l.* for Greifswald to 2,000*l.* for Göttingen. In Austria, although the existence of so many different languages in the empire makes special demands on the university libraries, the Government assistance has hitherto been exceedingly limited. We notice, however, that in a late session of the Reichstag a new policy has been adopted, and that the annual grants have been raised to 1,500*l.* for the Vienna library, 1,000*l.* for that at Prague, and 800*l.* for those in the other universities.

ST. PETERSBURG.—On January 1, 1878, the University at St. Petersburg numbered 1,425 students, thirty-seven more than last year. One-seventh are in the department of History and Philology, three-sevenths in Natural Sciences and Mathematics, three-sevenths in Law, and one-forty-seventh in Asiatic languages. The number of professors is ninety-three. The students are mostly very poor, and the pecuniary help given to them by the University amounted during the year to the sum of 12,000*l.*; besides which, a private society of former students paid the fees for eighty-one persons.

KIEFF.—The University celebrated, during the past month, the fifty-ninth year of its existence. Although so young it is well equipped with all the necessary adjuncts of a university, and its medical faculty is regarded as the first in Russia. The number of students at present is 773, an increase of 160 on the previous year. The majority are in the medical faculty. As in the other Russian universities, the students are recruited principally from the poorer classes, 203 being freed from the payment of lecture-fees, and 123 in addition receiving stipends amounting in the total to 36,000 roubles. A high school for ladies is at last to be opened at the University.

SCIENTIFIC SERIALS

Reale Istituto Lombardo di Scienze e Lettere. Rendiconti, vol. x. Fasc. xix.—Reduction of chlorates to chlorides without intervention of the so-called nascent state of hydrogen (second part), by M. Tommasi.—On the cooling of pulverulent metallic solids, by M. Cantoni.—On temperature in relation to actual energy and the state of aggregation, by M. Grassi.—Measurement of the resistance and graduation of any galvanometer, by M. Grassi.—A school experiment and means of evaporating rapidly large quantities of liquid, by M. Brugnatelli.

Fasc. xx.—Other experiments on the evaporation of a liquid, by M. Cantoni.—Hypertrophy and hyperplasia, by M. Sangalli.—On the first and most recent appearance in Lombardy of the Beccafico of Provence.

Kosmos, November, 1877.—On the relation of Greek nature-philosophy to modern natural science, by Prof. F. Schultze. Part 1, on the Ionic physiologists and the Pythagoreans.—On a mathematical law applicable to the theory of mutation, by J. Delbœuf.—On the variations of size of coloured floral envelopes, and their effect on the natural selection of flowers, by Hermann Muller.—A turning point in the early history of the human race, by J. H. Becker. Part 1, on the state of things preceding the turning point (before the discovery and use of fire).

December, 1877.—F. Schultze, on the relation of Greek natural philosophy to modern natural science, part 2, discussing Heraklitus and the Eleatic school.—W. Preyer, on the nature of life.—Fritz Müller, observations on Brazilian butterflies, part 3, dealing with the evolution of the Maracuja butterflies, and the phenomena presented by their larvæ, pupæ, and adult forms.—A. Maurer, on the origin of articulate sounds.—J. H. Becker, on the separation and reunion of races.—The number also contains a review of Mr. Darwin's work on the different forms of flowers, by Hermann Muller.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, February 6.—Prof. P. M. Duncan, F.R.S., president, in the chair.—James Adey Birds, Rev. George E. Comerford [illegible]ey, M.A., Lieut.-Col. H. H. Godwin-Austen, Sir Willoughby Jones, Bart., and Henry Richard Ladell, M.A., were elected Fellows of the Society.—The following communications were read:—On some foraminifera from pleistocene beds in Ischia, by M. Ernest Vanden Broeck. Preceded by some geological remarks by A. W. Waters, F.G.S.—On the influence of the advent of a higher form of life in modifying the structure of an older and lower form, by Prof. Owen, C.B., F.R.S. In this paper the author, after referring to the general question of the modification of the structure of organic forms produced by the action of external influences, indicated that, in connection with this, changes in the nature of the prey of carnivorous animals ought to be taken into consideration. He inferred that cold-blooded aquatic animals formed a much greater proportion of the food of mesozoic than of neozoic crocodiles, and pointed out as connected therewith the well-marked distinction between the amphicœlian and procœlian type of vertebræ respectively characteristic of the two groups. The procœlian character of the trunk-vertebræ better adapts that part of the body to be sustained and moved in air, and may be connected with the incoming in tertiary times of mammalian prey inducing the crocodiles to rush on shore. The mesozoic crocodiles were encased in a much stronger and more complete dermal armour than their successors, doubtless for their protection from the great ichthyosaurs, pliosaurs, &c., which co-existed with them; but as these passed away at the close of the secondary epoch, the armour of the procœlian crocodiles has become more scanty, and the diminution of weight and rigidity thus caused would favour progression in air, and the rapidity of movement required for capturing mammalian prey on land. The difference in the position of the palato-nares, and in other related gular and palatal structures, between the mesozoic and neozoic crocodiles is apparently connected with the power possessed by the latter of holding submerged a powerful mammal without permitting the access of water to the posterior nostrils and windpipe of the crocodile; and hence the author is inclined to ascribe a fish-diet even to those massive-jawed crocodiles from the Purbeck (such as *Goniopholis crassidens* and *simus*), which in some respects might seem fitted to grapple with large and active mammals. The small size of the upper temporal apertures in tertiary and existing crocodiles is regarded by the author as a further proof in the same direction; these apertures are reduced by the progressive increase of the osseous roof of the temporal vacuities, which again is correlated with increase in the bulk and power of the temporal muscles, the main agents in biting and holding. The differences in the length and strength of the jaw, as a rule, testify in the same direction. Further, the fore limbs in mesozoic crocodiles are shorter than in neozoic species, indicating that the former were more strictly aquatic in their habits; the forelimbs in all crocodiles being closely applied to the body during rapid swimming, and small limbs being less obstructive than larger ones. On the other hand, they would be less efficient as a means of progression on land, and hence it may be inferred that the advent in tertiary times of mammals frequenting the water-side, tempting the crocodiles to make a rush upon the land to seize such passing prey, would lead to such strenuous action of the fore-limbs as would account for the increased size and power of those organs in the neozoic species. The author concluded with some remarks upon the influence of the above considerations upon our views as to the generic divisions of crocodiles.—Notes on a supposed crocodilian jaw from the coral rag of Weymouth, by E. Tully Newton, F.G.S., of H.M. Geological Survey. In this paper the author describes what he believes to be a fragment of a lower jaw of a crocodilian, obtained from a greyish brown sandy grit, probably belonging to bed 3 of Messrs. Blake and Hudleston's Sandford-Castle section.—Note on two skulls from the Wealden and Purbeck formations indicating a new sub-group of crocodilia, by J. W. Hulke, F.R.S., F.G.S. The author described a crocodilian skull obtained by Mr. H. Willett, F.G.S., from the Hastings sands near Cuckfield, in Sussex, and identified by that gentleman with *Goniopholis crassidens*, Owen; and another from the Purbecks near Swanage, in the collection of the British Museum, which he further compared with a third specimen from Brook, in the Isle of Wight.

February 15.—Annual General Meeting.—Prof. P. M. Duncan, F.R.S., president, in the chair.—The Secretaries read the Reports of the Council and of the Library and Museum Committee for the year 1877. The Society was described as in an exceedingly prosperous condition, and the income of the year was stated to have considerably exceeded the expenditure. The number of Fellows elected was fully up to the average. The Report further announced the receipt of a bequest of 500*l*. under the will of the late Mr. C. Lambert, which sum, with 150*l*. of the surplus of income, had been invested in consols for the benefit of the Society.—The Wollaston Gold Medal was presented to Dr. Thos. Wright, F.R.S., for his varied palæontological researches.—The President then presented the balance of the proceeds of the Wollaston Donation Fund to Mr. W. J. Sollas, M.A., F.G.S., in recognition of his careful morphological and mineralogical studies upon the fossil Spongida.—The President next handed the Murchison Medal to Mr. Warington W. Smyth for transmission to Dr. Hanns Bruno Geinitz, of Dresden for his researches in the geology and palæontology of the palæozoic and cretaceous formations of Saxony; and the balance of the proceeds of the Murchison Geological Fund to Mr. H. Hicks, F.G.S., for transmission to Mr. Charles Lapworth, F.G.S., for a most important communication upon the Silurian rocks of the South of Scotland, and the graptolites contained in them.—The President next handed to Mr. J. W. Hulke, F.R.S., the Lyell Medal and part of the Lyell Fund for transmission to Mr. George Busk, F.R.S., as a token of the Council's appreciation of his merits as a palæontologist.—The balance of the proceeds of the Lyell Fund was handed to Dr. Oldham, F.R.S., F.G.S., for transmission to Dr. W. Waagen, of Vienna, and who was lately on the Geological Survey of the East Indies. Dr. Waagen's labours in India have commended themselves to the Council on account of their great merit and interest.—The President then proceeded to read his anniversary address, in which he dwelt in considerable detail upon the influence of advanced morphological and zoological investigations upon our palæontological ideas and upon the geological inferences founded upon them.—The ballot for the Council and Officers was taken, and the following were duly elected for the ensuing year:—President, H. C. Sorby, F.R.S. Vice-Presidents: R. Etheridge, F.R.S., John Evans, F.R.S., Prof. J. Prestwich, F.R.S., Prof. A. C. Ramsay, F.R.S. Secretaries: Prof. T. G. Bonney, M.A., Prof. J. W. Judd, F.R.S. Foreign Secretary: Warington W. Smyth, F.R.S. Treasurer: J. Gwyn Jeffreys, F.R.S. Council: H. Bauerman, Prof. T. G. Bonney, M.A., Prof. W. Boyd Dawkins, F.R.S., Prof. P. Martin Duncan, F.R.S., R. Etheridge, F.R.S., John Evans, F.R.S., Henry Hicks, W. H. Hudleston, M.A., Prof. T. McKenny Hughes, M.A., J. W. Hulke, F.R.S., J. Gwyn Jeffreys, F.R.S., Prof. T. Rupert Jones, F.R.S., Prof. J. W. Judd, F.R.S., J. Morris, J. A. Phillips, Prof. J. Prestwich, F.R.S., F. G. H. Price, Prof. A. C. Ramsay, F.R.S., R. H. Scott, F.R.S., Warington W. Smyth, F.R.S., H. C. Sorby, F.R.S., Admiral T. A. B. Spratt, C.B., F.R.S., Rev. T. Wiltshire, F.L.S.

Zoological Society, February 19.—Prof. Mivart, F.R.S., vice-president, in the chair.—The Secretary exhibited the skin of a fine adult cassowary, which had been obtained at Wandammen, on the eastern coast of the Bay of Geelvink, New Guinea, and had just been acquired by the British Museum. The species to which it belonged was believed to be undescribed, and was proposed to be called *C. altijugus*, from its peculiar high-peaked helmet.—Mr. P. Geddes read a memoir on the mechanism of the odontophore in certain mollusca. In this paper the view of Cuvier—that the movements of the radula depend upon those of the underlying cartilages—was substantially revived, arguments being adduced against the more recent theory of Prof. Huxley, that it runs like a chain-saw, the cartilages merely forming a pulley-block. The use of bacteria as food by *Lymnæus* was also described by the author in this paper.—Prof. A. H. Garrod, F.R.S., read some notes on the anatomy of *Tolypeutes tricinctus*, and gave remarks on other *Dasypodidæ*. A new form of *Tolypeutes*, allied to *T. conurus*, was proposed to be called *T. muriei*.—A communication was read from Mr. J. H. Gurney, F.Z.S., containing notes on a specimen of *Polyborus*, lately living in the Society's Gardens.—A communication was read from Mr. D. G. Elliott, F.Z.S., containing the results of his study of the *Pteroclidæ*, or family of sand grouse. Nine species of *Pterocles* and two of *Syrrhaptes* were recognised as composing the family.—Messrs. F. Du Cane Godman and Osbert Salvin gave descriptions of new species of diurnal lepidoptera from Central America.—A communication was read from Mr. R. Bowdler Sharpe, giving an account of a small collection of birds from the Ellice Islands.—Mr. Edward R. Alston read a note on the dentition of *Cuscus*.—A communication was read from Mr. T. F. Cheeseman, containing the description of three new species of Opisthobranchiate mollusca from New Zealand.—Dr. F. Day communicated some remarks on the paper read by Mr. Whitmee at the last meeting of the Society, on the manifestations of fear and anger by fishes.—A communication was read from the Marquis of Tweeddale, F.R.S., containing an account of a collection of birds made by Mr. A. H. Everett, in the Island of Negros, Philippines.—A second communication from the Marquis of Tweeddale contained the description of a new species of the genus Buceros, proposed to be called *B. semigaleatus*, from the Island of Leyle, Philippines.

Mineralogical Society, February 19.—Mr. H. C. Sorby, F.R.S., president, in the chair.—The president read a valuable and important paper on the determination of the minerals in thin sections of rocks by means of their refractive indices. In this paper he showed how the refractive indices might be determined with great accuracy in sections less than $\frac{1}{300}$ of an inch in thickness, cut for ordinary microscopic purposes.—The Rev. T. G. Bonney then read a paper on some specimens of Gabbro from the Pennine Alps, in which he pointed out the great changes which these rocks had undergone, and their similarity to the rocks of the Lizard district in Cornwall.—Mr. J. H. Collins read a paper on the classification of minerals, in which he advocated a primary chemical and a secondary mixed system of classification. This paper elicited an interesting discussion. Specimens in illustration of their papers were exhibited by the president and by the Rev. T. G. Bonney.—Dr. Foster exhibited specimens of carbonate of bismuth, and other minerals from new Cornish localities.

Photographic Society, February 12.—Annual Meeting.—James Glaisher, F.R.S., president, in the chair.—A silver progress medal was awarded to Capt. Abney, R.E., F.R.S., for having made the greatest advance in the science of photography during the past year.—Capt Abney exhibited a very large positive photograph taken from one of Janssen's negatives of the sun, which were taken by a five-inch telescopic objective of about seven feet focal length, corrected for the chemical, but not for the visual rays.—Mr. Edward Viles exhibited the micro-photographic apparatus by which the large photograph (recently seen at the exhibition) of the proboscis of the blow-fly enlarged 200 diameters, was taken, the mechanism and use of the heliostat being minutely described.—Capt. Abney also exhibited and described two other forms of heliostats which he had used.

PARIS

Academy of Sciences, February 25.—M. Fizeau in the chair.—The President announced the opening of a subscription for a statue to M. Leverrier. The following papers were read:—On the carburation of nickel by the process of cementation, by M. Boussingault. Though combining with carbon, nickel does not acquire, like iron, the properties found in steel; nor is the cemented nickel rendered less oxidable. (M. Becquerel is examining its magnetic properties.)—On a new product of oxidation of lead, and on some phenomena of dissociation, by M. Debray. Sesquioxide of lead is transformed, gradually at 350°, and rapidly at 440° into minium, which is not susceptible of being hyperoxygenated in air, or even in pure oxygen. It cannot be said that any compound formed directly will necessarily undergo a limited decomposition at a given temperature. Imitation of the characteristic cupules and erosions found on the surface of meteorites in an industrial operation, by action of a rapid current of air on incandescent stones, by M. Daubrée. In a new mode of manufacture of Portland cement, the stones raised to white heat are subjected to a current of cold air; the specimen (furnished by M. Hauenschild) showed a surface very like that of meteorites.—Note on a new *brochure* of M. Hirn on music and acoustics, by M. Faye.—On the recent communication of M. Broun, and a note of Mr. Jenkins relating to sun-spots and terrestrial magnetism, by M. Faye.—On telephones with battery, by M. Du Moncel. The author hopefully calls attention to MM. Pollard and Garnier's attempts to strengthen the sound; the sending telephone being on Edison's graphite system, while the receiver is a Bell telephone connected to the induced wire of a Ruhmkorff coil, the battery currents being passed through the primary wire. With pretty strong currents words can be heard 50 or 60 ctm. from the mouth of the telephone, and musical sounds several metres off.—The vibrations of matter and the waves of the ether in ebullition, by M. Favé.—Report on a memoir of M. Haton de la Goupillière.—On the lines generated in movement of a plane figure.—On some consequences of the constitution of the solar spectrum, by M. Cornu. If the sun's outer layer contain, like aerolites, a large amount of iron vapour, this metal probably has an appreciable action on our terrestrial magnetic phenomena. The central part of the earth seems to be formed of much denser materials than the crust, probably metallic matter; and the probable common origin of bodies of the solar system seems to point to iron being largely present, which would explain the earth's action on the magnetic needle. Again, the solar protuberances may correspond to illumination by induction (large magnetic masses being in rapid motion) of rarefied gaseous masses—an illumination easily produced in our laboratories by means of the weakest mechanical actions.—On differential actions of the first order and the first degree, by M. Darboux.—On the temporary variation of permanent magnetism, by M. Gaugain.—When a system (tube and core, or even full bar) magnetised at ordinary temperature is raised to 300° or 400°, the weakening of the magnetism is not exclusively due to a part of this magnetism being destroyed; it arises in part from the *inverse* magnetism being developed in the tube under influence of heat.—On the action of fluoride of boron on organic matters, by M. Landolph.—Transformation of bromated hydrocarbons of the series of ethylene into bromide of acids of the fatty series, by simple addition of oxygen, by M. Demole.—Analysis of the sulphurous waters of Aix, in Savoy, and of Marlioz, by M. Willm.—Action of oxygen on anatomical elements, by M. Bert. These elements are nourished by reducing the oxyhæmoglobic combination (and similarly to the butyric ferment); but if their substance be penetrated artificially with chemically free dissolved oxygen, they become incapable of taking oxygen from the matter which furnished it before, and die by a kind of asphyxia; in a word they are *anærobies*.—On local variations of the pulse in the forearm of man, by M. Mosso. He experiments with a *hydrosphygmograph*, which is a modification of his plethysmograph. The effects during intellectual effort, sleep, &c., are described.—On lactic fermentation of sugar of milk, by M. Richet. It seems that the gastric juice, by its dissolving action on caseine and perhaps another action yet unknown, gives lactic fermentation a surprising activity and rapidity.—Classification of Cestoides, by M. Perrier.

VIENNA

Imperial Academy of Sciences, January 3.—On the velocity of propagation of spark-waves, by MM. Mach, Tumlirz, and Kogler.—On orthogonal substitutions and some related to them, by M. Igel.—On ballooning, by M. Ettalp.—Three experiments with the telephone, by M. Sacher.

THE LOCUST PLAGUE IN AMERICA

The Locust Plague in the United States; being more particularly a Treatise on the Rocky Mountain Locust, or so-called Grasshopper, as it occurs East of the Rocky Mountains, with Practical Recommendations for its Destruction. By Charles V. Riley, M.A., Ph.D., State Entomologist of Missouri, &c. With 45 Illustrations. (Chicago: Rand, McNally, and Co., 1877.)

THE greater part of this treatise has already appeared in the Entomological Reports published annually for some years past by Mr. Riley, as State Entomologist for Missouri, in which the information was given piecemeal from time to time as it was acquired. The whole is now brought together in a connected and systematic form, and we have in it a very complete and valuable treatise on the different kinds of locusts, whether species or varieties, which have proved destructive in North America. Ever since the discovery and colonisation of that continent the new settlements have been from time to time subject more or less to scarcities resulting from the invasions or migrations of these insects. These have gradually, however, become scarcer and scarcer, and confined more and more to the interior as the insects retreated before the advancing wave of civilisation and cultivation, until now their ravages do not extend eastwards beyond the 16th or 17th degree of longitude west of Washington; in other words, the regions lying to the east of the Mississippi are now nearly free from them, and it is only in those lying to the west of that river that their propagation and migrations take place on such a scale as seriously to affect the property and prosperity of the settlers. It is not that the species originally inhabiting the eastern coast have been gradually pushed back to the interior, but that the species peculiar to it have been reduced in number in the cultivated districts, and their *rôle* has been successively taken up by other species lying more inland as civilisation has gradually advanced. The species on which that mission has now devolved are two or three that have their home and permanent breeding-place in the Rocky Mountains—we say *permanent* in contradistinction to temporary breeding-place, because when they make their migrations, they often rest and breed at its furthest limit, the brood returning in the following year to the country from which their parents came, although not necessarily by the same route. The route by which they have hitherto invaded the countries to the east of their proper home in the Rocky Mountains has been from north-west to south-east. That by which the fresh-bred swarms sprung from the invaders have made their way back again next year, has been from south east to north-west, but not absolutely in the same line by which their parents came, but either parallel to it or slightly divergent. Their course o invasion has been carefully traced for many years by M Riley and others, and the fact of their return on their footsteps in this way is beyond question; but it is also beyond doubt that the new brood does not go back so strong or so numerous as their parents came. Their constitution appears to be sapped by the change of climate or condition of life; they are feeble and infested by parasites, so that a large proportion of them die a natural death—a consideration which doubtless explains why the vast swarms which have passed from one country to another in all ages and in all quarters of the globe, seem never to have made good a permanent footing in the country they have invaded; at all events never in numbers at all corresponding to the force of the intruders. This is no doubt but small consolation to settlers living on the borders of a locust-stricken land, but it is better than none—they would be still worse off if the locusts to remain as a permanent incubus instead of only coming occasionally as a ravaging horde.

Of the amount of injury done by the invading hosts, specially during the more recent invasions of 1873 and following years, Mr. Riley gives a striking account. Where a territory of hundreds of miles in extent is struck with desolation in a few days or weeks through the ravages of an insect, it is scarcely possible to speak of it without exaggeraion, and some qualification will almost certainly have to be made upon any estimate of the amount of damage supposed to have been sustained, especially when, as here, we know how little the data on which the estimates are founded are to be relied on. In Great Britain we have now an elaborate machinery by which reliable agricultural returns are obtained; the land, or most of it, has been measured and mapped out; the best means are taken to obtain true and correct returns, and when obtained they are checked by competent and trustworthy experts; so that no error of any magnitude can well creep in without detection. It is otherwise on the prairies west of Missouri. The admirable United States Surveys, although sufficiently perfect and on a sufficiently large scale to answer all general purposes, have no pretensions to such detail as we have adopted in our Ordnance Survey Maps, and no attempt is made to give the acreage of the different plots in cultivation (which, besides, would be useless, as it is an uncertain quantity, varying every year). At the best, therefore, there are no other means of estimating either the amount in cultivation or the amount of damage inflicted on it than an empirical estimate furnished by the farmers themselves, a mode of calculation open to many objections, and requiring much allowance. Still, giving the widest margin, enough remains behind to satisfy the hungriest appetite for startling results. If actual starvation did not come in the locusts' train, poverty and distress did. In 1874 the loss to three exposed, although thinly-peopled, states, Wyoming, Dakota, and Montana, is said to have been fifty millions of dollars; and in 1875 it was calculated that about three-quarters of a million of people were made sufferers on a strip of about twenty-five miles broad along the banks of the Missouri, from Omaha to Kansas.

Mr. Riley gives many statistics on such points. His information regarding the habits of the locusts and their enemies, and the best way of dealing with them, is also ample; and his scientific descriptions and natural history of the species in all their stages leave nothing to be desired. He even touches upon their value as food either with or without wild honey, and gives the results of his experience as to the best mode of cooking them. During a visit that he paid to this country, some two or three years ago, he brought some dried potted specimen with him; but that was scarcely fair play to the locusts, and we shall not say what we thought of them. Let us still be just. If we are to condemn them, let it only be after a trial when they are fresh and good. We have indeed tried them in their native country, pounded up with acorns and mashed into balls by the digger Indians of California; but then acorns would destroy any dish for civilised food, so that we prefer to leave the question of their culinary merits an open one for some gastronomic jury, stipulating only for the right of challenging Mr. Riley, as one of its members, on the score of undue favour and partiality arising from too intimate an acquaintance and familiarity with the individuals under trial.

A further contribution to the subject treated of by Mr. Riley has reached us in the shape of the first two *Bulletins* of the United States Entomological Commission.

ANDREW MURRAY

ABNEY'S TREATISE ON PHOTOGRAPHY

A Treatise on Photography. By W. de Wiveleslie Abney, F.R.S. (London: Longmans and Co., 1878.)

ALL those interested in this most attractive study will welcome Capt. Abney's treatise on photography. Those who wish to become acquainted with the scientific principles on which the practice of photography depends will find in the opening chapters a clear and concise description of the theory of sensitive substances, and of the action of light on various compounds, whilst by studying the closing chapters of the volume they will be able to make themselves acquainted with the present state of our knowledge on the important subjects of actinometry, photo-spectroscopy, and the interesting discoveries made by the author and others on the sensitiveness of different salts, and the methods employed for obtaining pictures of the various portions of the spectrum. On the other hand, the artist photographer will find ample matter for interest in the chapter in which Capt. Abney most successfully lays down the rules which must guide the production of an artistic picture, pointing out the special difficulties under which the photographer lies in the choice of subjects in order to avoid incongruity or inartistic massing of light and shade, and showing the best mode of lighting and arranging the picture by choosing the right point of view for the camera. As an illustration of Capt. Abney's happy style and power of artistic treatment, we may quote the following description of a landscape:—

"In the next picture, we have the distance, or perhaps more strictly speaking, the middle distance as the point of interest. The horizon line is kept in the weakest part, the centre, of the picture. The trees in the foreground are so grouped that they frame the view with dark masses, relieved by the light foliage of some of the nearer bushes and shrubs. The foreground finishes at a distance of about ¼ from the bottom. More of it would take away from the value of the middle distance, as it would place it in the weakest part of the picture viz., centrally; less of it would have rendered the picture bald, and have cut off part of the deeper shades which are so valuable in giving the effect of distance to the stream beyond. This picture would have been spoilt had the camera been so placed as to give more top foliage, since the bough which now partially crosses the picture at about ⅝ the height, would have caused an ugly division, and also the tops of the distant trees, and the sky would have appeared. This latter, in views such as that under criticism, is objectionable, as patches of white give the eye an inclination to wander off towards it, and it would have been an insufficient precaution to have printed in clouds from another negative, owing to the difficulty that would exist in subduing at the same time the lights on the leaves of the near trees. As it is, the picture is in pictorial focus. By placing the stream to the right or left, the balance would have been wanting, and its general direction would have been altered to such an extent as to have given a feeling that it was a subsidiary part of the picture instead of an essential."

Another important section of the work is devoted to the necessary, but unavoidably dry descriptions of the very numerous photographic processes and manipulations now in vogue, of the construction of apparatus, and a statement of the general laws of geometrical optics so far as concerns the principles on which the construction and use of photographic lenses depend. On all these subjects we find Capt. Abney's statements clear and concise.

Then again no book on photography would be complete without an explanation of the various processes of photo-lithography and photo-engraving, and accordingly we find a short account of the more important of these interesting methods of reproducing photographic effects. To one of these photo-relief printing processes, that discovered by Warnerke, with, we believe, the author's co-operation, we would especially draw attention, the picture being remarkable for the beauty and delicacy, as well as for the force and depth of its tones. The details of this process are not yet published; it cannot, however, be doubted that it is capable of producing the finest effects of a steel or copper plate engraving.

It is, however, the scientific side of Capt. Abney's book which will especially interest the readers of NATURE. The explanation of the effect of vibration as setting up chemical change in the molecule is clearly set forth in Chapter III. The case in which the atoms are in a stable though verging on an indifferent equilibrium as with the sensitive mixture of chlorine and hydrogen, being well illustrated by the equilibrium of a frustum of a pyramid standing base uppermost on as narrow section of the base as we please. In these cases a very small amount of work is needed to make the systems take up more stable positions. Then "extending our previous illustration, supposing we had a row of such frusta of pyramids, and that it was found that one pellet of a number (all being of equal weight) when striking one frustum with a certain velocity was able to cause it to fall, and also that in every case the accuracy of aim was undoubted, and that in falling one frustum did not strike its neighbour, then at any interval after the commencement of a bombardment the amount of work expended in projecting the pellets could be compared by simply counting the number of frusta which had fallen" (p. 12). The question of the action of vibrations synchronous with the oscillations of the molecule on the stability of the molecule is next discussed, and the explanation rendered clear by a description of Rankine's well-known contrivance of the heavy and light pendulums. The difference between the decomposition of explosives and of bodies employed for photographic purposes in respect to the nature of the disturbing vibrations is thus pointed out. Explosives are affected by long wave rays, photographic actions as a rule being only set up by waves of short length. A description of the remarkable negative or reversing action effected by the red rays on the sensitised plate, first observed by H. Draper, is found in Chapter XXXIV. A partial explanation of this very interesting fact is given by the results of experiments lately made by Capt. Abney (*Phil. Mag.*, January, 1878), which show that the image can be rendered undevelopable by the oxidation of the altered silver compound forming it. Chastaing has also recently announced that he finds rapidity of oxidation promoted by the red rays. It is thus easy to see that the sensitive salt of silver which had been altered in chemical composition by a slight exposure to white light, would become oxidised where the red rays fell upon it, and that, in consequence, where the dark Fraunhofer's lines in the ultra red spectrum fell, the plate would remain unaffected and the presence of these invisible bands would become apparent.

Another subject of great interest, that of the production of coloured photographic images, is being attacked experimentally by Capt. Abney. The results of the experiments in this direction by Becquerel and Niepce de St. Victor are well known, and many of the visitors to the Loan Exhibition will remember the coloured photograph of dolls dressed in coloured clothes shown by the latter chemist. Abney believes that these tints are rather to be ascribed to different stages of oxidation of the film, than, as has hitherto been supposed, to the colours of thin plates. Then, again, on the subject of the recent discoveries by Vogel, Waterhouse, and others, as to the production of a film sensitive to the red rays by the addition of a red dye to the collodion, Capt. Abney has something original to say. He has found that the addition of certain resins, albumin, and other organic bodies, when combined with silver, tends to lower the limit of the impressible spectrum and the place of maximum sensibility; so much so, indeed, that it is possible to obtain an unreversed impression of the thermal spectrum. A beam of light was allowed to pass through ruby glass, and the spectrum was then thrown on a sensitised plate in the ordinary manner, and a visible impression of rays in the red was obtained far beyond the limit of the visible spectrum, as is seen by a figure in the volume.

Enough has been said to show the value of Capt. Abney's treatise both from the scientific and artistic points of view. If we are to speak on the part of amateur photographers we would express a hope that the subject of the explanation of defects in negatives and their cure may be more fully treated of in the next edition. It is perhaps difficult for an accomplished photographer like the author to appreciate the difficulties of a beginner in the art, but the mere mention of some of the defects met with in negatives does not always, as the author states, suggest the cure to minds unfamiliar with the niceties of manipulation and procedure which to the expert come as a matter of course. We congratulate Capt. Abney on the appearance of this most useful volume.

H. E. R.

OUR BOOK SHELF

Archæological Researches at Carnac, in Britanny. By James Miln. (Edinburgh: David Douglas.)

THIS beautiful book reflects great credit on its author. It would be difficult in the recent literature of archæology to point out a more salient example of the great gain which is sure to accrue to that branch of science from the introduction of the true scientific spirit, and attention to details. Carnac, in most people's minds, is associated with Druidical circles, and it was to see the wonderful alignments there that Mr. Miln visited the place. But while in the region the author was particularly struck with the remains belonging to a very different time, which were pointed out to Mr. Miln by a French archæologist. They are termed the mounds of the Bossenno. With characteristic energy Mr. Miln, who was determined to explore, endeavoured to buy in order that he might explore the better. In this, however, he was foiled, beset by too many difficulties. The permission to explore which he subsequently obtained does not appear to have been a very complete one, and after this big book full of matter our author states that much still remains to be done.

The results of the excavations so carefully carried out by Mr. Miln show that we have here the remains of a Gallo-Roman settlement, and he has reconstructed for us out of its ashes the condition of the people in former times. He has been enabled to give us precise information as to their food and the degree of luxury in which they indulged. Their worship, their ceremonies, and modes of manufacture, and the exact times between which the colony was in a flourishing condition are also fully discussed. He traces the local worship of Venus Genetrix, at the Mont St. Michael, in a most interesting manner. One of the oldest constructions which remains in Britanny is the chapel of St. Agatha. On the vault of the apse a few years ago was discovered one of the most curious frescoes which the Romans have left in Britanny. It represents Venus rising from a blue sea, surrounded by fishes and dolphins. This church, now dedicated to St. Vener, is styled "Ecclesia Sancti Veneris" in a twelfth century charter.

The beautiful illustrations comprise not only almost everything which was found, but large coloured plates of the chief coloured designs rescued here and there.

All antiquaries will do well to lay to heart the remarks on ancient pottery made by Mr. Miln *à propos* of his finds in the excavation which he designates A. He shows abundantly how much caution is requisite in such inquiries and how a careful sifting of facts brings order into what at first sight appears a hopeless jumble of objects. It is curious that some of the pottery he found there is similar to some in the Guildhall Museum, which was found at a depth of forty-two feet, when the ground was excavated for the foundations of the Royal Exchange.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

The Telephone

IN his interesting paper (NATURE, vol. xvii. p. 283) Mr. F. J. M. Page communicated as the result of his experiment to obtain indication of currents from a telephone by means of a mercury capillary tube, that the motion of the mercury was "always towards the end of the capillary." In the repetition of this experiment before the Physical Society on Saturday, February 16, Mr. Page found, however, that the mercury moved persistently in the opposite direction.

In the December (1876) number of the *Phil. Mag.* I showed that the motion of mercury in contact with dilute acid through which a current passes, is due to rapid circulation of the mercury set up by deoxidation of one part of its surface whilst another part is being oxidised; and that a very slight difference in the degree of oxidation is sufficient to produce an appreciable electromotive force.

When the mercury tube of the so-called electrometer is set up, the two surfaces of the mercury in contact with the acid are, I believe, almost always electrically unequal, that in the capillary being less oxidised than the other, and therefore positive to it. When the circuit is closed, a feeble current passes which, if it were strong enough, would move the mercury forwards. When a telephone is in action in the circuit, its equal and opposite currents combine alternately with the mercury current which strengthens the impulses in one direction and weakens those in the other; so that, whilst the sum of the telephone and mercury currents may be able to move the mercury in one direction, the difference of these currents is not able to move it in the other. Hence, I believe, arise the motions in question.

It of course follows that if, by accident, the potentials of the two mercury surfaces were equal, the telephone currents would produce no movement whatever in the mercury. Moreover if by variation of temperature, or by difference of strength of acid at the contact faces, or otherwise, the mercury surface in the capillary is rendered negative to the other surface, the accidental current set up will be in the opposite direction, and the tendency will be for the mercury to recede in the tube, as was observed in the experiment performed before the Physical Society.

Mr. Page's experiment will, I have no doubt, suggest a means of deducing the potentials of the telephone impulses.

Robert Sabine

AFTER reading the experiments of Prof. Forbes on the telephone, in NATURE, vol. xvii. p. 343, it occurred to me, as probably it has done to others, that this instrument might be employed in comparing the electrical resistances of wires. Accordingly, two weak cells were connected with the ordinary form of Wheatstone's bridge, and the telephone placed in the position usually occupied by the galvanometer. The current was rendered intermittent by a small electromagnetic apparatus belonging to an electric bell; the bell itself having been detached, the intermitter was placed in a separate room, and connected by long wires with the battery and bridge. The German silver wire of the bridge, having a resistance of ·2 ohms, was further lengthened at each end by resistance coils of ten ohms, and it was found that with a little practice one could easily compare two resistances of about two ohms within at least 1,000th of the true ratio.

It was found better to attach the sliding piece to the battery rather than the galvanometer, and it was exceedingly curious to notice the effect of moving the sliding piece so as to gradually diminish the difference of potential at the two terminals of the telephone, the sound diminishing until at last there seemed to be only a slight *uneasiness* produced in the ear, which ceased whenever the contact between the sliding piece and the German silver wire was broken. I have no doubt whatever that with a more delicate instrument than the one employed, which was apparently not nearly so sensitive as that used by Prof. Forbes, one could compare with considerable accuracy electrical resistances in this manner. Of course the telephone could also be employed instead of the galvanometer, in comparing the electromotive forces of batteries, and it is my intention to make more experiments in this direction.

By using a tuning-fork made to vibrate by electricity and a Helmholtz's resonator in conjunction with the telephone, the accuracy of testing may no doubt be largely increased.

Herbert Tomlinson

1. IF the cavities above and below the iron disc of an ordinary telephone are filled with wadding, the instrument will transmit and speak with undiminished clearness.

2. On placing a finger on the iron disc opposite the magnet, the instrument will transmit and speak distinctly. It only ceases to act when sufficient pressure is applied to bring plate and magnet into contact.

3. Connecting the centre of the disc by means of a short thread with an extremely sensitive membrane no sound is given out by the latter when a message is transmitted.

4. Ten telephones were connected as represented in the following diagram, on the principle of a battery joined for surface or quantity.

From transmitter—

A, B, C, &c., telephones.

On receiving a message from the transmitter *it could distinctly be heard through any of the ten instruments, although the current had been split up ten times.* (I have no doubt that a greater number of telephones might thus be joined with almost equal effect; from want of instruments I have not been able to find out the limit.)

The following experiments were made with a double telephone, constructed by a battery of horse-shoe magnets with iron cores at their ends. The wires on the bobbins were wound in opposite directions, as on an ordinary electro-magnet.

5. *On connecting the similar poles of the coils (as + and +) and joining the remaining similar poles (as − and −) to line wires the instrument both transmitted and spoke with equal distinctness.*

6. On placing the armature on the horse-shoe magnet no loss of power was perceptible in either transmitting or receiving, nor was there any increase of power on augmenting the number of magnets.

7. If the inner and outer coils of an induction coil are respectively connected with a transmitting and receiving instrument, sound can be distinctly transmitted in either direction.

8. If an ordinary Leyden jar is interposed in the line wire, one end being in contact with the inner, the other with the outer coating, sound can be transmitted, but it is much weakened in strength.

9. Bringing the iron cores of the double telephone in contact with the disc and pressing with the fingers against the plate on the other side, a weak current from a Daniell cell produced a distinct click in the plate, and on drawing a wire from the cell over a file which formed part of the circuit, a rattling noise was produced in the instrument.

Experiments No. 1, 2, 3, and 9 tend to show the absence of mechanical vibration. For the Experiments Nos. 4 and 5 I fail to find a reasonable explanation. No. 6 shows that strength of the magnet has nothing to do with the force of the sound produced, the latter being simply the result of a difference of two opposing forces. Nos. 7 and 8 require no explanation.

The above notes are taken from a paper read by me before the Priestley Club on February 16.

Bradford Grammar School — Aurel de Ratti

IN NATURE, vol. xvii. p. 164, there was a notice of a telephonic alarum in the shape of a tuning-fork. This, however, requires a fixed and special telephone. The following method of attracting attention requires neither. I venture to send it you, as I have seen no notice of any one having tried it; but I can scarcely believe it to be the case, as the thing would suggest itself to any one studying the instrument. It is to include a magneto-electric machine in the circuit, when turning the handle produces a series of taps in the telephone audible at a considerable distance. I have not tried it for any long distance—merely fifty yards. The magneto-electric machine was placed in the observatory, and the telephone, or rather a battery of three telephones, in my study. The noise was heard at the further end of my dining room, the door of which faces that of the study.

Rugby — A. Percy Smith

EXPERIMENTING with a pair of telephones the other day, I thought I would try if it were possible to utilise underground pipes as conductors. I therefore connected one terminal of each instrument with the gas and the other with the water-pipes, in two houses placed about thirty yards apart, and found that it was possible to carry on conversation by means of the instruments thus connected. The voices were not as distinct as if wire had been used, but singing was very plainly heard. I have not had the opportunity of trying a longer distance; perhaps some of your readers may test the matter further.

Bury, Lancashire — William Stockdale

'Mimicry in Birds"

OWING to the special meaning of late attached to the word "mimicry" by naturalists, the above heading seems liable to mislead when applied to the fact mentioned by Mr. J. Stuart Thomson (page 361). In answer to his inquiry perhaps you will allow me to quote the following from the fourth edition of Yarrell's "British Birds" (vol. ii. p. 229) with respect to the starling.

"[illegible] song is as imitative as that of the vaunted Mocking-bird, and in nothing perhaps is it more grateful than in the reminiscences it brings to our homes of its wilder associates far afield; for Starlings consort with many kinds of birds, learn their notes and frequently mingle them in their own strain."

And then as a foot note:—

"Thus the well known wail of the Lapwing, and the piping note of the Ringed Plover may be heard in places wholly unsuited to the habits of those birds. Messrs. Matthews mention Starlings imitating the cry of the Kestrel, Wryneck, Partridge, Moorhen, and Coot among other birds (Zool. p. 2430). Saxby says that in Shetland the notes of the Oyster-catcher, Golden Plover, Redshank, Curlew, Whimbrel, and Herring-Gull, are perfectly mimicked. Mr. Hooper, of Upton near Didcot, informs the editor that Starlings in that neighbourhood will render exactly the characteristic cry of the Quail and the Corn-Crake. The common sounds of the poultry-yard are often copied with more or less accuracy, and a Duck may be heard to quack, a Hen to cackle, and a Cock to crow from the topmost bough of a tall tree."

It follows that if a Starling can so well imitate the notes of the above-named birds, it would have still less difficulty with those of species much more nearly allied to it, as the Blackbird, Chaffinch, and Sparrow. ALFRED NEWTON

Magdalene College, Cambridge, March 9

The "Geographical" and the Public

QUITE accidentally this evening I noticed in NATURE that Capt. Evans was to read a paper on the Magnetism of the Earth, before the Royal Geographical Society at the London University. Having devoted considerable attention to the subject I was desirous of hearing the paper and hurried up to town. I found, however, that I could not obtain admittance without an order. I offered payment but that was useless. I explained to the doorkeeper that I had come a long distance, was most anxious to hear the paper, and did not know until then the terms of admission, otherwise, as many of my friends are Fellows, I could have supplied myself with the necessary order.

I offered my card and suggested that it might be sent in to Sir Henry Rawlinson, to whom I was known, or to the Secretary or some other official, but to all my endeavours there was a curt, not to say pert, reply.

It occurred to me that if I waited a short time some friend might possibly make his appearance and help me in my "pursuit of knowledge under difficulties." I had not waited many moments when I noticed the door-keeper despatch on an errand a lad who supported him. I was weak-minded enough to imagine he had relented, and that some official would come to my aid. An official did certainly come back with the lad—it was a policeman! who gave me a look which I interpreted to mean, "If you don't be off I'll 'run you in.'" A few words in a very low tone passed between the doorkeeper and himself, and as I had no desire to spend the night in Vine Street station, I departed, feeling that this was an *argumentum ad hominem* which I could not resist. X.

Temple, March 11

Hearing and Smell in Insects

ALL that I have observed leads me to believe that any sensitiveness shown by insects to sound is due to a diffused sensibility to vibration rather than to a differentiated sense like our own. This will sufficiently explain the behaviour of J. C.'s moths (NATURE, vol. xvii. p. 45), and my own larvæ (NATURE, vol. xvii. p. 102). In the one case the ringing glass, and in the other the vibrant wood of the feeding-box communicated the alarm. If anyone, an hour after his kitchen has been left in darkness and quiet, will enter it as gently as possible, without shoes or light, and then, having no contact with anything, other than the unavoidable one of his sock-muffled feet with the floor, will speak suddenly and sharply, I believe he will find that not a cockroach shows any signs of alarm. If, on the other hand, he should drop something heavy abruptly, or enter with his usual step in boots, there is a stampede; but even then nothing to compare with the commotion caused by the introduction of light.

As to smell, there can be no doubt, it seems to me, that it is a very finely differentiated sense; residing, I suspect, to a great extent, in the antennæ, and probably capable of detecting qualities in substances of which our own analogous sense gives us no warning. The ichneumon flies are an example in point. One of the larger of these alighted inside my open window in the sunshine this afternoon, and I noticed, as often before, the incessant play of his antennæ as he hunted restlessly to and fro, apparently in search of larvæ, or pupæ, concealed under the wood. As the prey of some members of this tribe are always so hidden, and the egg is accurately laid therein, by means of the long ovipositor, without the aid of sight, some other sense, in great perfection, must guide them in their quest. But here is a quite conclusive instance.

I saw in Athens, March, 1864, in the collection of Mr Merlin, then our vice-consul there, placed in juxta-position in one drawer in his cabinet, a wasp and spider, of which he told me that that species of spider is the habitual prey of that species of wasp, and that he hunts him by scent, nose down, precisely like a hound. He witnessed himself the chase from beginning to end in the case of the actual specimens I saw. It occurred in his own house, and was continued for some time, and across, as I understood him, more than one room. The spider, as soon as he found himself marked down, showed the greatest terror, running hither and thither, with many doubles and turns. These the wasp—a long, thin-bodied variety—followed accurately, turn by turn, never quitting the spider's track for an instant, recovering, when at fault, like a dog, until, after an exciting chase, he seized his exhausted prey, and the keenly-interested human observer secured both pursuer and victim. HENRY CECIL

Biegner, Bournemouth, March 2

OUR ASTRONOMICAL COLUMN

THE TOTAL SOLAR ECLIPSE OF JULY 29.—Prof. Newcomb has lately issued empirical corrections to Hansen's Lunar Tables, which he proposes to employ in the American Ephemeris for 1883. The errors of the tables have now attained such magnitude, and exhibit so steady an increase, that it becomes necessary to apply corrections, even though they may be of the otherwise unsatisfactory nature of empirical quantities, and it is probable that Prof. Newcomb may not be the only superintendent of an ephemeris who will adopt this course pending the formation of new lunar tables at, it may be hoped, no distant period.

At the time of the total solar eclipse which traverses the United States in July next, Mr. W. Godward finds the correction of the longitude of the moon deduced from Hansen's tables to be − 9″·5, and the correction of the latitude + 0″·9, according to Newcomb. Applying these corrections to the moon's place, and adopting Leverrier's diameter of the sun, with a somewhat reduced diameter of the moon from that given by Hansen's tables, which corresponds well in the calculation of eclipses, the following equations are found, which may be expected to give the times of beginning and ending of the total phase with considerable accuracy for any point not far distant from Denver, Colorado, the most important place traversed by the belt of totality.

$$\cos w = \text{[illegible]} - [1 \cdot 5211] \sin l + [1 \cdot 71\text{[illegible]}] \cos l \,.\, \cos (L + 216° \; 48' \cdot 2)$$

$$t = \text{[illegible]}^{h} \; 54^{m} \; 34 \cdot 2^{s} \mp [1 \cdot 93963] \sin w - [\text{[illegible]}] \sin l - [1 \cdot 02402] \cos l \,.\, \cos (L + \text{[illegible]}° \; 25' \cdot 6).$$

Here *l* is the *geocentric* latitude of the point, L its west longitude from Greenwich, to be used with a *negative* sign, and the quantities within square brackets are logarithms; *t* is the Greenwich mean time of beginning or ending of totality, according as the upper or lower sign of the second term is used, [1·93963] sin *w* representing the semi-duration of the total phase; and applying the longitude of the place for which we are calculating in the usual way, the local mean times result.

As an example of the method of using formulæ of reduction similar to the above, which is frequently a matter of doubt to the uninitiated, we may find from them the local mean times of beginning and ending of the total eclipse in 106° 14′ W., and 40° 23′ N., which, according to the *Nautical Almanac* elements, is the position of the central eclipse at 1[illegible]h. 28m. Greenwich mean time.

The reduction of the geographical to the geocentric latitude (which may be taken from tables found in many astronomical works—in Loomis's "Practical Astronomy," for instance, or in the *Berliner Jahrbuch* for 1852) is − 11″·4 and consequently l = 40° 11′·6.

W. long. … …	− 106° 14′	… …	− 106° 14′
Constant … …	+ 216° 48′·2	… …	+ 256° 25′·6
A … …	+ 110° 34′·2	B …	150° 11′·6

Constant …	− 1·85211	Constant …	1·71204
Log. sin l …	+ 9·80981	Log. cos l …	9·88302
		Log. cos A …	− 9·54574
	− 1·66192		1·14080
No. …	− 45·9111		
	− 13·8293	No.	13·8293
	− 59·7404		
Constant …	+ 59·7050		
Sum … …	− 0·0354		
Log. cos w …	− 8·54900		
w … … …	92 1′·7		

Constant	1·93963	Constant	3·70066	Constant	− 3·82402
Log. sin w	9·99973	Log. sin l	9·80981	Log cos l	9·88302
				Log. cos B	− 9·93837
	1·93936				3·64541
	87·0 No				

Constant … … …	$9^{h}\ 54^{m}\ 34^{s}$
G.M.T. of middle of totality	$10^{h}\ 28^{m}\ 18^{s}\cdot 2$
Long. W. *in time* …	$7^{h}\ 4^{m}\ 56^{s}\cdot 0$
	$3^{h}\ 23^{m}\ 22^{s}\cdot 2$
Semi-duration … … …	$1^{m}\ 27^{s}\cdot 0$
Totality begins … … …	$3^{h}\ 21^{m}\ 55^{s}\cdot 2$ Local M.T.
,, ends … … …	$3^{h}\ 24^{m}\ 49^{s}\cdot 2$ Local M.T.

The duration of the total eclipse is therefore 2m. 54s. and the middle at 10h. 28m. 18s. G.M.T.; the *Nautical Almanac* has 2m. 55s. and 10h. 28m., so that the corrections which we have introduced into the calculation have had but very insignificant effect. It may be added that when cos w is found greater than unity, and therefore impossible, the place for which the calculation is made is beyond the zone of totality.

THE STAR LALANDE 31266 7.—Mr. J. E. Gore writes with reference to this object, which in the reduced Catalogue of Lalande appears as a *first* magnitude, with position for 1800 (by a mean of the two observations), R.A. 17h. 1m. 22·36s., N.P.D. 45° 57′ 21″·6, and suggests that it may prove to be a remarkable variable, since it is "shown 6m. in Flammarion's edition of Dien's Atlas." The introduction of such a star into the Catalogue is easily explained, and in fact is rather an old story. The two observations on p. 353 of the "Histoire Céleste" were really observations of Capella (*Chèvre*, as Lalande calls it) *sub polo*, and were erroneously reduced to 1800, as though the star had been observed above pole. It is singular that these two observations should have given rise to the introduction of a spurious star, since there are eight other observations of Capella *sub polo* in the same year, 1790, between April 19 and July 24, of which no use has been made by the computers in their reduction of the stars of the "Histoire Céleste." There is no sixth magnitude in the position of the reduced catalogue.

MINOR PLANETS.—There are yet two more members to be added to this group—No. 184, discovered by Herr Palisa at Pola, on February 28, and No. 185, by Prof. Peters, at Clinton, U.S., on the following night. The *Berlin Circular*, No. 86, contains elements of Nos. 181-183.

BIOLOGICAL NOTES

INLAND FISHERIES, AMERICA.—We are indebted to Mr. Theodore Lyman, one of the United States Commissioners on Inland Fisheries, for an early copy of the Twelfth Annual Report to the Commonwealth of Massachusetts. Among other interesting facts we gather from it that there is still a mystery about the young of the Californian salmon (*Salmo quinnat*), for, notwithstanding the hundreds of thousands that have been put into New England waters, no one has been able to say with certainty that a single smolt has been seen. In reference to the true salmon (*S. salar*), it is pleasant to know that the return of mature salmon to the waters of the Merrimac last year (1877) commences a new era in the history of fish-culture in America. From the observations taken many of these mature salmon were from eight to ten pounds weight each, and were from the parr put into the river in 1873; but some were seen from fifteen to eighteen pounds weight, and these were most probably the result of the first parr put into the river in 1872. From 1872 to 1876 upwards of 830,000 parr were put into the river, and hundreds of fine fish were seen passing up in the spring of 1877; and, so says the report, "it will be seen that what we have so long fought for, what the mass of people here have generally considered mere theories, visions of men who suffered from fish on the brain, has been fully substantiated. It is true it took a little longer than was at first thought, but now Massachusetts knows that while she was the first of the States to take an interest in fish-culture, so she has been the first to demonstrate the certainty of a good return, and she can restock those rivers where the fish have been for a long time killed out."

THE DEVELOPMENT OF NERVES.—Dr. A. M. Marshall is continuing his careful researches into the earliest stages of nerves in vertebrate embryos. He has recently published in the *Quarterly Journal of Microscopical Science* some of his latest results, obtained from embryos of the common fowl, treated with picric acid. He describes a distinct neural ridge at the top of the cerebro-spinal tube in the middle cerebral track, before it has even closed in, the embryo being barely two days old in development. This ridge afterwards becomes continuous along the whole brain and great part of the spinal cord, and many of the nerves undoubtedly arise from it. It appears in the highest degree probable that the olfactory nerve originates from the anterior part of this ridge; but Dr. Marshall is quite certain that there is no special olfactory vesicle in the chick. This is directly contrary to the received teaching, which speaks of an olfactory lobe of the brain, and does not compare the olfactory with other nerves. Dr. Marshall believes that the common olfactory nerve is really the nerve of the anterior cranial segment. The third nerve is for the first time developmentally traced by Dr. Marshall, and he finds it to be a strictly segmental nerve. The seventh and eighth nerves (facial and auditory) are shown to have a common origin; the auditory is really a branch of the facial. The history of the vagus nerve (pneumogastric) is regarded as suggesting very strongly that it is equivalent to several spinal nerves, and not merely to one.

FRENCH POLYZOA.—An important contribution to the history of a number of species of marine polyzoa will be found in a memoir on "Les Bryozoaires des Côtes de France," by M. L. Joliet, of the Zoological Laboratory at Roscoff, a spot so well known to every tourist in Britanny.

A résumé is given of the remarkable works that have appeared on the structure of the animals of this group in England, Sweden, and Germany, as well as in France. The interesting question of the part played by, as well as of the origin of, the brown bodies (*groddskaplar* of Nitsche) is very fully gone into. The specialist will know what a subject of debate lies here. Hincks, our best English authority, believing them to be special formations elaborated from the substance of the polyp; Claparède, that they are products of secretion; Nitsche that they are only the remains of decaying polyps. With the last of these views our author agrees: "Le corps brun est un résidu, le reste de la matière qui constituait un polypide après que celui-ci a subi la désorganisation." The nature of the nervous colonial system in the polyzoa is also investigated at full length, and M. Joliet feels compelled to doubt if this so-called system merits this name. The arguments for and against are too technical for us to epitomise. The growth and development of several species were specially investigated, and the entire memoir, to which is appended a list of the species collected (74) at Roscoff during the summers of 1876 and 1877, is well worthy of the attention of all interested in the study of these small but interesting polyps. It will be found in the recently-published *Archives de Zoologie Expérimentale* (Tome 6, No. 2).

STRUCTURE OF LINGULA.—Mr. E. Morse, Professor of Zoology in the Imperial University of Tokio, Japan, has discovered many facts quite new to science in the life history of this interesting form of Brachiopods. Perhaps the most important is his discovery of the auditory capsules. In the species of Lingula investigated, their position and general appearance recall those in certain tubicolous annelids as figured by Claparède. He has also cleared up many points in regard to their circulation, and maintains the absence of anything like a pulsatory organ, the circulation being entirely due to ciliary action.[1] In describing the habits of this species he mentions that, while partially buried in the sand, the free border of the pallial membranes join so as to leave but three large oval openings, one in the centre and one on either side; the bristles then arrange themselves so as to form these openings into funnels which arrest the mucous secretion from the animal, and a continuous current is to be seen passing down the side funnels and escaping by the central one. They can bury themselves very quickly in the sand, and the peduncle agglutinates a sand tube. Prof. Morse exhibited specimens in Boston on December 19, 1877, which had been brought living from Japan: the water had been only changed twice since August 19, and yet none had died. Their viability, therefore, seemed to be great. As Prof. Morse is now on his way back to his professorial duties at Japan, he will have the opportunity of still further prosecuting his researches into the structure and habits of these forms so interesting to both the palæontologist and zoologist.

GEOGRAPHICAL NOTES

NEW GUINEA.—A recent number of *Il Movimento* contains a letter from the Italian traveller, D'Albertis, dated from Thursday Island, in Torres Straits, on January 8 last, in which some account is given of his last expedition into New Guinea. Leaving Port Somerset on May 3, 1877, in his steam launch, *Neva*, it was not until the 21st of that month that he succeeded in entering the *embouchure* of the Fly River, where he was well received by the natives. But such was not the case when the *Neva* had advanced a little further up the river, for on June 1 a sudden and unprovoked attack was made on the vessel, and one of the Chinese crew seriously wounded. These attacks were frequently repeated during the further ascent of the river, though always successfully repelled without casualties. In July and August, when far in the interior, the expedition seems to have been unmolested, but on the subsequent descent of the stream the banks were found again beset by daring and hostile parties of warriors, whose efforts to hinder the return of the expedition brought on frequent skirmishes. Signor D'Albertis was also much inconvenienced by the dissensions of his crew, the greater part of whom deserted him, leaving only five to manage the vessel and to repel the attacks of the natives. Two of these also left him on returning to the mouth of the river, leaving him to accomplish the dangerous navigation of Torres Straits with only the engineer and one sailor. Eventually, however, with aid received from the native teachers on some of the islands in Torres Straits, he succeeded in reaching Thursday Island—now the calling-place of the Queensland mail steamers—on January 4 last. As regards the results of the expedition no details are given in this letter, but from certain expressions employed it would appear that gold in some quantity was obtained. Of this we shall, no doubt, be duly informed before long, as also of the zoological discoveries in which Signor D'Albertis has on former occasions been so successful.

NEW AFRICAN EXPEDITION.—It is rumoured that the Council of the Royal Geographical Society are likely soon to send out a new expedition for the exploration of Africa. The region between Mombasa and Mount Kenia and Victoria Nyanza is mentioned as the probable field of this expedition.

AFRICAN EXPLORATION.—Abbé Debaise, who intends to cross Africa from Zanzibar to the Congo, has received a credit of 100,000 francs from the French government. This sum was voted to him on the proposal of M. Perrin, a radical member, who was supported by M. Gambetta, the leader of the Liberal party. The Abbé will leave Paris for Marseilles in a few days, and thence proceed to Zanzibar. He will be supported by the new Geographical Society of Marseilles, and its president, M. Rambaud, the large Zanzibar trader. News has lately been received in Berlin from the African traveller, Dr. G. A. Fischer, who has traversed since last autumn the tropical regions lying opposite the island of Zanzibar. Despite the hostility of the natives, he has succeeded in making a large number of scientific observations, and has gathered a large collection of zoological specimens, which are now on the way to Berlin. During the present month he starts on a journey up the river Tana.

CAPTAIN ELTON.—We have already referred to the great loss sustained by geography, by the death of this energetic traveller in Ugogo; he died of sunstroke. Mr. Cotterill and Captain Elton had reached this place from the north end of Lake Nyassa, the country traversed being described as very interesting and new to geography. They found the sources of the Ruaha, Usanga, and other affluents of the Lufigi, the Myembe tributary being specially worthy of notice. Mr. Cotterill's narrative will be looked for with interest, as well as Capt. Elton's diaries and map, which have been sent home. The latter, at the time of his death, was H.M. Consul in Portuguese East Africa, and had done work in various parts of the world. He had done good service in helping to clear up the history of African Copal, the produce of *Trachylobium Hornemannium.*

ANCIENT MAPS OF CENTRAL AFRICA.—M. Richard Cortambert, one of the librarians of the National Library in Paris, has discovered in that establishment a gilt globe, dated 1540, and showing apparently that the course of the Congo was known then to have almost the same direction as given to it by Mr. Stanley. There has also been discovered in the public library of Lyons a globe of 1701, on which are traced in detail the geography of the sources of the Nile and Congo. This globe is said to have been executed by the Fathers

---

[1] Semper has already fully demonstrated this fact.—F. P. W.

Placide, of St. Amour, and Crispinien, of Toulon, and by the two Brothers Bonaventura and Gregory, all of the Order of St. Francis. Father Gregory, it is said, was the celebrated Lyonnaise geographer, Henry Marchand. In speaking of these discoveries at the Paris Geographical Society, M. R. Cortambert showed that there was nothing extraordinary in them. From the fifteenth century most of the maps make the Congo issue from a great mass of water in the interior of the African continent. No doubt all the information in these old maps was furnished by the Portuguese. M. Vivien de St. Martin is also of this opinion. The Portuguese traders were quite *au courant* with the geography of the interior of Africa, and all the maps, even that of Fra Mauro (15th century) represent the Nile issuing from lakes to the south of the equator, and give an idea of the course of the Congo, similar to that made known by Stanley. M. St. Martin reminded the Society, moreover, that Ptolemy himself had indicated three immense lakes in the centre of Africa from which issued the Nile and the Congo; only in his map these lakes are placed much too far south. Father Kircher, in his "Mundus Subterraneus," published at Amsterdam in 1653, gives a map showing four large lakes, from one of which, called Zaire, both the Nile and the Congo are made to issue. Kircher states that he obtained his information from the General Procurator of the Jesuits for these provinces, who lent him a manuscript of Father Païs. This manuscript may possibly be still preserved in the Jesuit College at Rome.

PARIS GEOGRAPHICAL SOCIETY.—Besides the medals to Mr. Stanley and M. St. Martin, the Paris Geographical Society will give medals to Dr. Harmand for his exploration of the Mekong and the coast of Anam, and to M. Ujfalvy for his travels in Turkestan. The *Bulletin* for December contains an important geographical and statistical article on Kashgar, compiled from various sources by M. J. B. Paquier, an itinerary on the Yang-tsze from Shung-shing to Yun-nan-fu, by M. Rocher, and a valuable summary of the geodetic work of the Russian Geographical Society in Asia, by Col. Chanoine.

NOTE ON THE DISCOVERY OF THE LIQUEFACTION OF AIR AND OF THE SO-CALLED PERMANENT GASES

IN the Notes on "Recent Science," in this month's *Nineteenth Century*, the writer, in an account of the results of the researches of M. Pictet and M. Cailletet on the condensation of the so-called permanent gases, draws attention to the long-neglected paper of Mr. Perkins "On the Compressibility of Water, Air, and other Fluids," an abstract of which, and apparently the only one with which the writer is acquainted, appeared in Thomson's *Annals of Philosophy, N. S.*, vol. vi., 1823. The paper was intended for the Royal Society, but, being mislaid, was not read at the appointed time. Either it or a second paper was, however, brought before the society on June 15, 1826, and appears in the *Philosophical Transactions* for that year. In this paper, as in the brief record in the *Annals*, Mr. Perkins announces that he had effected the liquefaction of atmospheric air, and other gases, by a pressure of upwards of 1,000 atmospheres, and fully describes the apparatus which he had employed, which is, in principle, very similar to that of M. Cailletet. He thus describes his results in the case of aeriform fluids:—

"In the course of my experiments on the compression of atmospheric air by the same apparatus which had been used for compressing water, I observed a curious fact which induced me to extend the experiment, viz., that of the air beginning to disappear at a pressure of 500 atmospheres, evidently by partial liquefaction, which is indicated by the quicksilver not settling down to a level with its surface. At an increased pressure of 600 atmospheres, the quicksilver was suspended about $\frac{1}{8}$th of the volume up the tube or gasometer; at 800 atmospheres it remained about $\frac{1}{3}$ up the tube; at 1,000 atmospheres, $\frac{2}{3}$ up the tube; and small globules of liquid began to form about the top of it; at 1,200 atmospheres the quicksilver remained $\frac{3}{4}$ up the tube, and a beautiful transparent liquid was seen on the surface of the quicksilver, in quantity about $\frac{1}{2000}$ part of the column of air. On another occasion a second tube was charged with 'carburetted hydrogen' and subjected to pressure; it began to liquefy at about 40 atmospheres, and at 1,200 atmospheres the whole was liquefied."

Mr. Perkins goes on to say: "These instances of apparent condensation of gaseous fluids were first observed in January, 1822, but for want of chemical knowledge requisite to ascertain the exact nature of the liquids produced, I did not pursue the inquiry further; and as the subject has been taken up by those who are eminently qualified for the investigation, I need not regret my inability to make full advantage of the power I had the means of applying."

Mr. Perkins's observations seem to have attracted little attention at the time they were published, and have since been, apparently, almost forgotten. Although they do not in the least detract from the great merit of M. Cailletet's work, they undoubtedly have their place in the history of this subject of the liquefaction of the gases.

It may be worth while to point out that the statement that all the gases known to the chemist have now been liquefied is not strictly true. The most recently-discovered of these—phosphorus pentafluoride—has not yet been seen in the liquid state, although there is not the least reason for believing that it will constitute an exception to the general law.

T. E. THORPE

HELMHOLTZ'S VOWEL THEORY AND THE PHONOGRAPH

THE following experiments with the phonograph are of interest as throwing light on the nature of vowel sounds:—

Let a set of vowel sounds, as A, E, I, O, U (pronounced in Italian fashion) be spoken to the phonograph in any pitch, and with the barrel of the instrument turned at a definite rate. Then let the phonograph be made to speak them, first at the same rate, and then at a much higher or lower speed. The pitch is, of course, altered, but the vowel sounds retain their quality when the barrel of the phonograph is turned at very different rates. We have made this experiment at speeds varying from about three to one, and we can detect no alteration in the quality of the sounds.

According to Helmholtz, the characteristic quality of each vowel is given by the prominence of a constituent note or notes, of definite or approximately definite absolute pitch, in the sounds uttered. Now obviously, the absolute pitches of the constituents of the vowel-sounds in the above experiment were all altered in the same proportion, so that the absolute pitch of the prominent notes varied greatly; but yet the vowel quality was unchanged. This experiment, therefore, appears to give results in contradiction of Helmholtz's theory as we understand it.

At the same time we have found, in the course of experiments, of which a full account will shortly be communicated to the Royal Society of Edinburgh, that if a scale be sung to the phonograph with one vowel sound, such as O, the wave-form of the marks on the tinfoil does not remain unchanged at all pitches. We have not yet had time to analyse the curves so obtained into their harmonic constituents. Such an analysis will show whether the changes we have observed in the wave-form as the pitch rises, are due to a change in the relation of the amplitudes of the constituents present, or only to a variation of phase.

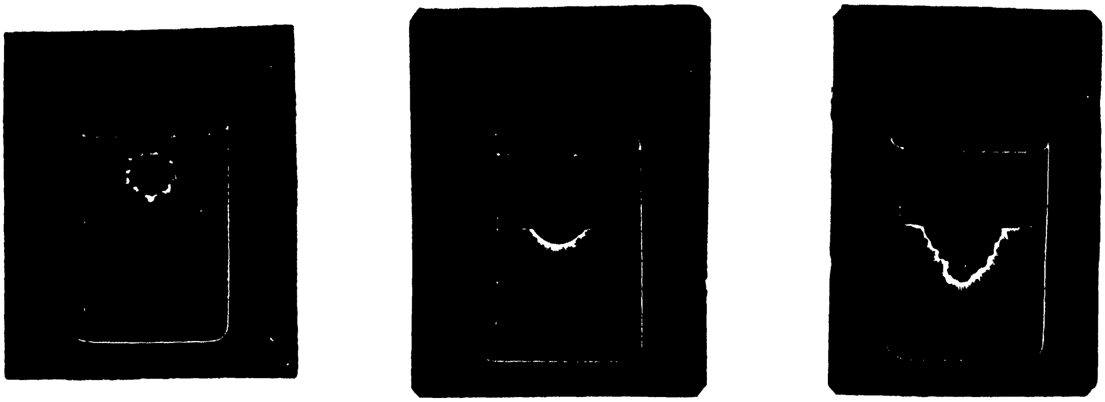
Edinburgh, March 11

ELECTRICAL ANALOGIES WITH NATURAL PHENOMENA[1]

II.

POLAR AURORÆ.—The experiments of De la Rive have already shown the connection of polar auroræ with terrestrial magnetism; but they do not explain all the circumstances which accompany auroræ. In M. Planté's experiments the electric current, in presence of aqueous vapour, yields a series of phenomena altogether analogous to the various phases of polar auroræ.

If the positive electrode of the secondary battery is brought into contact with the sides of a vessel of salt water, we observe, according to the distance of the film from the liquid, either a corona formed of luminous particles arranged in a circle around the electrode (Fig. 8), an arc bordered with a fringe of brilliant rays (Fig. 9), or a sinuous line which rapidly folds and refolds on itself (Fig. 10). This undulatory movement, in particular, forms a complete analogy with what has been compared in auroræ to the undulations of a serpent, or to those of drapery agitated by the wind. The rustling noise accompanying the experiments is analogous to that sometimes accompanying auroræ; it is caused by the luminous electric discharge penetrating the moisture. As in auroræ, magnetic perturbations are produced by bringing a needle near the circuit, the deviation increasing with the development of the arch. Auroræ are produced by positive electricity; the negative electrode produces nothing similar.



FIGS. 8, 9, 10.—Coronas and luminous arcs.

Globular Lightning.—To study the effects produced on distilled water, M. Planté increased the tension of the current, combining twenty secondary batteries, composed each of forty couples, and forming a total of 800 secondary couples, whose current of discharge was nearly equal to that of 1,200 Bunsen elements.

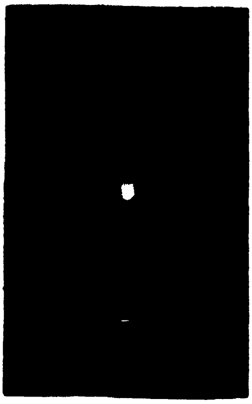


FIG. 11.—Flame produced over distilled water by an electric current of high tension.

When the current of this combination of batteries is made to act on distilled water, he finds, first, in much greater intensity, the effects already observed by Grove, by means of 500 elements of his nitric acid pile. The positive electrode being inserted in the distilled water, he obtains, by approaching the negative platinum wire to the surface of the water, and immediately raising it, a yellow flame, almost spherical, of about two centimetres in diameter (Fig. 11). The platinum wire, two millimetres in diameter, melts; the flame is formed by the rarefied incandescent air, by the vapour of the metal of the electrode, and by the elements of the vapour of water; spectral analysis shows clearly the presence of hydrogen.

If, to avoid the fusion of the metal, we diminish the intensity of the current by interposing a column of water in the circuit, the spark appears under the very compact form of a small globe of fire from eight to ten millimetres in diameter (Fig. 12). On raising the electrode a little more, this globe takes an ovoid form; luminous blue points, whose number varies continually, arranged in concentric circles, appear at the surface of the water (Fig. 13). Rays of the same colour soon issue from the centre and join these points (Fig. 14). At intervals the rays take a gyratory movement, now in one direction, now in another, describing spirals (Figs. 15 and 16). Sometimes the points and the rays disappear all on one side, and varied curves, formed by the movement of those which remain, are figured on the surface of the liquid. Finally, when the speed of the gyratory movement increases, all the rays vanish, and only blue concentric rings are seen (Fig. 17). The rings are found to be the last term of these transformations which are very curious to follow with the naked eye or with a telescope, and constitute a veritable electric kaleidoscope.

The production of these figures is explained by the great mobility of the arcs or luminous threads which compose the ovoid light, formed between the water and the electrode. On examining with care this particular form of spark, he finds that it is, in reality, a sort of voltaic brush discharge, analogous to the brush discharge of static electricity, but more dense on account of the greater quantity of electricity in play. These luminous threads being in a state of continual agitation, the points at which they encounter the surface of the liquid are constantly displaced, and form the rays observed. Their gyratory movement proceeds from the reaction due to the flowing of the electric flux. As to the rings, they are formed in a visible manner, under the eye of the observer, by the more and more rapid movement of the blue points, and by the persistence of the impression upon the retina.

---

[1] Continued from p. 350.

When the metallic electrode is positive and the distilled water negative, the spark still assumes externally an ovoid form; but the middle is traversed by a cone of violet light. When we employ two metallic electrodes we obtain a luminous spheroid, the interior of which is traversed by a brilliant line. This appearance corresponds to the spark, and the aureole of the spark seen in the discharges of an induction coil; only here the aureole occupies more space, in consequence still of the greater quantity of electricity. In fact, if we much increase the length of the column of water interposed, we do not obtain more than an arc or a straight line.

M. Planté therefore thinks globular lightning may result from an abundant flow of electricity in the dynamic state, in which quantity is joined to tension. The particular case where globes of lightning present slow movements or times of stoppage, is explained by the movement or the repose of the column of moist air strongly electrified and invisible, which serves as electrode. To imitate this effect it is sufficient, in one of the preceding experiments, to make the electrode oscillate, it being previously suspended under the form of a long pendulum above a basin full of water or a metallic surface, and to mask by a screen its lower extremity. We then see a little ball of fire move above the water or the conducting surface, and thus reproduce all the appearances of the natural phenomenon.

Fig. 12.—Globular spark produced over distilled water by an electric current of high tension.

Figs. 13 to 17.—Ovoid sparks and luminous figures produced over distilled water by an electric current of high tension.

Fig. 18.—Experiment reproducing the effect of waterspouts.

Waterspouts.—Cause a narrow stream of salt-water to flow from a funnel provided with a cock communicating with the positive pole of a battery of 400 secondary couples; the liquid is received in a basin containing the negative wire and below which is an electro-magnet (Fig. 18. As soon as the voltaic circuit is closed the stream appears furrowed with bright lines at its upper part and traversed by a luminous thread at its lower part. Sparks, illuminated aqueous globules, play with a rustling noise at its extremity, vapour is disengaged, and the liquid which surrounds the bottom of the stream takes a gyratory movement in the opposite direction to that of the hands of a watch if the pole of the electro-magnet is north, and in the same direction as the hands if this pole is south. The movement is rendered visible by light bodies spread over the surface of the water. If we contract the stream so as to avoid all solution of continuity at its lower part, the electric and luminous signs disappear almost entirely. The liquid is, nevertheless, heated, as is shown by a light vapour, and the gyratory movement is yet more pronounced and rapid. On extending the stream anew the electric manifestations re-appear as before.

This experiment reproduces the principal effects of waterspouts, the rustling which proceeds from them, the mist which is formed around them, the flashes of light which furrow them, the globes of fire which sometimes appear at their extremities—in such a way that, according to M. Planté, these meteors may be compared to electrodes of liquid or of vapour, from which escape to the earth or the sea the powerful electric currents of storm-clouds; and if no thunder follows it is because the conductor accompanies them to the ground, and there is in this case no proper electric discharge, no more than under the preceding conditions.

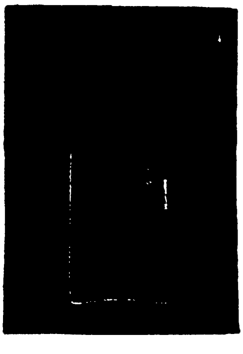

Fig. 19.—Electric bore.

The very formation of waterspouts, or the descent of these cloudy appendages towards the ground, has been connected by Brisson and Peltier with an electrostatic attraction between the clouds and the earth. We may add to this very natural attractive force an action of transport, of which dynamic electricity presents numerous examples, and which tends to facilitate the flow of water from an electrified cloud. The agitation of the liquid, the boiling of the waters at the point where these meteors encounter the surface of the sea, are explained not only by the descending movement itself, but also by the action of the electric current, which may repel or raise liquid masses like a breeze or an impetuous wind. If we support, in fact, the positive electrode against the sides of the vessel of salt-water communicating with the negative pole, we observe, besides the luminous streaks and jets abounding in vapour, a violent whirling of the liquid forming a sort of electric bore, which raises the water to the height of 1½ centimetre above its level (Fig. 19). When the current meets at certain points inequalities of resistance, it is divided and gives rise to several aqueous hillocks, as seen in Fig. 20.

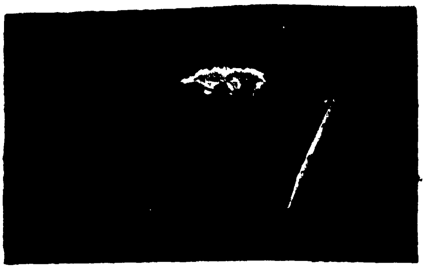

Fig. 20.—Electric bore or formation of liquid waves by the flow of a powerful current of dynamic electricity.

ON COMPASS ADJUSTMENT IN IRON SHIPS AND ON NAVIGATIONAL SOUNDINGS[1]

IV.—*On a Navigational Sounding Machine.*

THE machine before you is designed for the purpose of obtaining soundings from a ship running at full speed in water of any depth not exceeding 100 or 150 fathoms. The difficulties to be overcome are twofold: first, to get the lead or sinker to the bottom; and, secondly, to get sure evidence as to the depth to which it has gone down. For practical navigation a third difficulty must also be met, and that is to bring the sinker up again; for, although in deep-sea surveys in water of more than 3,000 fathoms' depth it is advisable, even when pianoforte wire is used, to leave the thirty or forty pounds' sinker at the bottom, and bring back only the wire with attached instruments, it would never do in practical navigation to throw away a sinker every time a cast is taken, and the loss of a sinker, whether with or without any portion of the line, ought to be a rare occurrence in many casts. The first and third of these difficulties seem insuperable—at all events they have not hitherto been overcome—with hemp rope for the sounding-line; except for very moderate depths, and for speeds much under the full speed of a modern fast steamer. It may indeed be said to be a practical impossibility to take a sounding in twenty fathoms from a ship running at sixteen knots with the best and best-managed ordinary deep-sea lead. Taking advantage of the great strength and the small and smooth area for resistance to motion through the water, presented by pianoforte wire, I have succeeded in overcoming all these difficulties; and with such a sounding machine as that before you the White Star liner *Britannic* (Messrs. Ismay, Imrie, and Co., Liverpool) now takes soundings regularly, running at sixteen knots over the Banks of Newfoundland and in the English and Irish Channels in depths sometimes as much as 130 fathoms. In this ship, perhaps the fastest ocean-going steamer in existence, the sounding machine was carefully tried for several voyages in the hands of Capt. Thompson, who succeeded perfectly in using it to advantage; and under him it was finally introduced into the service of the White Star Line.

The steel wire which I use weighs nearly 1¼ lbs. per 100 fathoms, and bears when fresh, from 230 to 240 lbs. without breaking; its circumference is only ·03 of an inch. By carefully keeping it always, when out of use, under lime water in the galvanised iron tank prepared for the purpose, which you see before you, it is preserved quite free from rust, and, accidents excepted, this sounding line might outlive the iron plates and frames of the ship. If the sinker gets jammed in a cleft of rock at the bottom, or against the side of a boulder, the wire is inevitably lost. Such an accident must obviously be very rare indeed, and there does not seem to be any other kind of accident which is altogether inevitable by care in the use of the instrument. The main care in respect to avoidance of breakage of the wire may be stated in three words—beware of kinks. A certain amount of what I may call internal molecular wear and tear will probably occur through the wire bending round the iron guard rod which you see in the after part of the instrument, when, in hauling in, the wire does not lead fair aft in the plane of the wheel, as is often the case even with very careful steering of the ship, but from all we know of the elastic properties of metals, it seems that thousands of casts might be taken with the same wire before it would be sensibly weakened by internal molecular friction. Practice has altogether confirmed these theoretical anticipations so far as one year of experience can go. My sounding machine has been in regular use in charge of Captains Munro and Hedderwick in the Anchor liners *Anchoria* and *Devonia* (Messrs. Henderson Brothers, Glasgow) for eleven months and seven months respectively, and in neither ship has a fathom of wire been lost hitherto, though soundings have been taken at all hours of day and night, at full speed, in depths sometimes as great as 120 fathoms. No break not explicable by a kink in the wire has hitherto taken place in any ship provided with the sounding machine. That it will bear much rough usage is well illustrated by one incident which happened in a cast taken from the *Devonia* running at thirteen knots. The sinker in falling from the wheel into the water accidentally fell between the rudder chain and the ship, and fifty fathoms or so had gone out before it was noticed that the wire was running down vertically from the wheel instead of nearly horizontally as it ought to have been by that time. The handles were immediately applied to the sounding wheel, and it was turned round to haul in without reducing the speed of the ship. Though the wire was bent almost at right angles round the chain until it was nearly all in, it was all got safely on board, as was also the cod-line with attached depth gauge, and the sinker at the end of it.

When soundings are being taken every hour or more frequently (as in the case of a ship feeling her way up channel from the 100 fathom line when the position is not known with sufficient certainty by sights and chronometers) the sounding wheel should be kept on its bearings in position; with the cod-line, depth gauge, and sinker, all bent on and ready for use. But in all other cases the wheel should be kept in its tank under lime water, and the cod-line with sinker and depth gauge attached should be kept at hand in a convenient place near the stand of the machine, which should be always fixed in position ready for use. With such arrangements, and methodical practice, as part of regular naval drill in the use of the sounding machine, one minute of time should suffice to take the sounding wheel out of its tank, place it on its bearings, adjust the brake cord, bend on the cod-line, and be quite ready for a cast. When the machine is to be shown to an inspecting officer the wheel ought to be in its tank of lime water when he asks to see a cast. It should be carefully noticed that the ring at the end of the wire is securely lashed by small cord to the hole provided for it in the ring of the wheel whenever the cod-line is unbent from the ring. If the wire and ring are allowed at any time to knock about slack on the wheel when the wheel is being moved to be set up for use or to be replaced under the lime-water there is a liability to some part of the wire getting a turn which may be pulled into a kink. One accident, at least, has happened in this way: the sinker dropped off carrying the cod-line and ring with it just as it was being let down from the taffrail for a cast. If the sinker had weighed 400 lbs.[1] it could not have broken the double wire next the ring without a kink.

A description of the machine and rules for its use are given in the accompanying printed paper of instructions, to which I have only now to add a few words regarding the depth gauge. Erichsen's self-registering sounding lead (patented in 1836), depending on the compression of air, might be used with my machine, but the simpler form before you is preferable as being surer. It too depends on the compression of air, but in it the extent to which the air has been compressed is marked directly on the interior of a straight glass tube by the chemical action of sea-water on a preparation of chromate of silver with which the tube is lined internally. Between the salt of the sea-water and the chromate of silver a double decomposition takes place. The chlorine leaves the sodium of the common salt and combines with the silver, while the chromic acid and oxygen leave the silver and combine with the sodium. Thus chloride of silver, white and insoluble, remains on the glass in place of the orange-coloured chromate of silver lining as far up as the water has been forced into the tube, and the chromate of sodium dissolved in the water is expelled as the air expands when the tube is brought to the surface.

---

[1] Report of paper read to the Royal United Service Institution, February 4, by Sir Wm. Thomson, LL.D., F.R.S., P.R.S.E., Professor of Natural Philosophy in the University of Glasgow, and Fellow of St. Peter's College, Cambridge. Revised by the Author. [The Council of the R.U.S.I. have kindly permitted us to publish Sir W. Thomson's paper in advance, and have granted us the use of the illustrations.—Ed.] Continued from p. 354.

[1] It weighs 22 lbs.

My navigational sounding machine was brought into practical use for the first time in the steamship *Palm*, belonging to Messrs. Charles Horsfall and Co., Liverpool, in a voyage to Odessa and back about a year ago, in command of Capt. E. Leighton. I cannot illustrate the use of the machine better than by reading to you an extract from a letter I received last April from Capt. Leighton, describing his experience of it in this first trial:—

"During the voyage in the *Palm* steamship, which has just come to an end, I took frequent opportunities of testing the sounding machine when I had a chance of cross-bearings to verify the depths as shown by chart, and always found it most accurate. For instance, going up through the Archipelago and just after clearing the Zea Channel, I got a good position by bearings, chart showing seventy-nine and seventy-six fathoms, two casts of your glass gave seventy-eight and seventy-five fathoms. In the Bosphorus also it gave capital results in thirty to forty fathoms water.

"The first real use I made of the machine was in the Black Sea during a fog which obscured everything. Wishing to make sure of my position I put the ship's head for the land and kept the machine at work. After running in to thirty fathoms at full speed I slowed down and went in to twelve fathoms, then hauled out to a convenient depth and put her on the course up the coast. When it became clear I found myself in a proper position, and no time had been lost by stopping to sound.

"How many shipmasters let hours go by without obtaining soundings either because of the delay or on account of the danger of rounding-to in heavy weather to get them, when, if they were provided with your sounding-machine, they could have their minds set at ease by having timely warning of danger, or by knowing that they were in a good position!"

I had myself very satisfactory experience of the usefulness of the sounding machine in coming up Channel running before a gale of south-west wind in thick weather, on the 6th and 7th of last August, on returning from Madeira in my yacht—a small sailing schooner of 126 tons. About 5 A.M. on the 6th I took two casts and found ninety-eight fathoms (sand and red spots) and 101 fathoms (sand and small shells). The mean with a correction of 2½ fathoms to reduce to low water, according to the state of the tide at Ushant at the time, was ninety-seven fathoms. Thenceforward I took a sounding every hour but one till eight in the evening. By writing these soundings on the edge of a piece of paper at distances equal according to the scale of the chart to the distances run in the intervals, with the edge of the paper always parallel to the course, according to the method of Sir James Anderson and Capt. Moriarty, I had fixed accurately the line along which the vessel had sailed, and the point of it which had been reached, with only a verification by a noon latitude. At 6 o'clock next morning, by the soundings and course, with proper allowance for the flood-tide, I must have been about thirteen miles magnetic south of the Start, but nothing of the land was to be seen through the haze and rain; and with the assistance of about ten more casts of the lead (by which I was saved from passing south of St. Catherine's) I made the Needles Lighthouse right ahead, at a distance of about three miles, at 2 P.M., having had just a glimpse of the high cliffs east of Portland, but no other sight of land since leaving Madeira and Porto Santo. In the course of the 280 miles from the point where I struck the 100 fathom line to the Needles, I took about thirty casts in depths of 100 fathoms to nineteen fathoms without once rounding-to or reducing speed; during some of the casts the speed was ten knots, and the average rate of the last 220 miles was a little over nine knots.

It is a pleasure to me to be able to add that the sounding machine has also been successfully used in the Royal Navy, Admiral Beauchamp Seymour and Capt. Lord Walter Kerr having kindly taken it on board H.M.S. *Minotaur* for trial last summer. Lord Walter Kerr wrote, on his return from Vigo, regarding it as follows:—

"The sounding machine is most serviceable. We have been using it constantly when running up Channel, from the time of crossing the line of soundings to the time of reaching Plymouth, and though running before a gale of wind with a heavy sea, at the rate of ten knots, we were able to get soundings as if the ship had been at anchor. We were able to signal to the squadron each sounding as it was obtained; thus, in thick weather, verifying our position by soundings without having to round the ships to."

THE ANALOGIES OF PLANT AND ANIMAL LIFE[1]

LET us begin our inquiry into the analogies of plant and animal life by comparing the egg of an animal with the seed of a plant. Let it be the ripe seed of a common plant, and the egg of a bird. Both seed and egg may be said to consist of the young creature and a supply of food which is stored up for its use, and is gradually exhausted as the young creature develops. Every one who has tried when a boy to blow a late bird's egg must have been painfully alive to the fact of its containing a young animal, and the egg we eat for breakfast may serve to remind us of the store of food which we diverted from its proper course of nourishing a young chicken.

Here is a diagram representing a section through the seed of a poppy, in which the young plant may be seen lying in its store of food containing a supply of carbohydrates and nitrogenous matter, which is consumed as the yolk of the egg is consumed by the young chicken. Other seeds, such as a bean, an acorn, or an almond, seem at first sight to consist of nothing but the young plant, and to have no store of food. The two halves into which a pea split are the two first leaves or cotyledons of the young plant, the embryo stem and root being represented by the little projecting mass lying between the two halves at one end of the seed. Here the store of food is laid up in the body of the young plant just as many young animals carry with them a store of food in the shape of the masses of fat with which they are cushioned; the two leaves which seem so gigantic compared with the rest of the plant are filled with nutriment, and perform the same function of supplying food for the growth of the seedling, which is performed by the mass of nutrient material in which the embryo of the poppy seed is embedded. Recent researches have shown that embryo plants are possessed of powers which even in the present day it seems almost ludicrous to ascribe to them. I mean powers of digestion. Gorup-Besanez,[2] a distinguished German chemist, found that in the germinating seed of a vetch a ferment exists similar to the ferment in the pancreatic secretion of animals—a secretion having the power of reducing both nitrogenous bodies and starch to a condition in which they can be utilised and absorbed by the tissues, so that the embryo plant behaves exactly as if it were a minute animal digesting and absorbing the store of food with which it is supplied. The power of digesting starch possessed by the embryo plant has been brilliantly demonstrated by van Tieghem,[3] who found that the embryo removed from the seed of the Marvel of Peru (*Mirabilis jalapa*) was distinctly nourished if placed in an artificial seed made of starch paste. He found that the starch paste was actually corroded by the young plant, proving that a digestive ferment had been at work.

This wonderful experiment is of special interest as proving that the digestive ferment is a product of the young plant itself, just as the digestive juice of an animal is a secretion from its stomach. It is indeed a striking thought that whether we grind up a grain of wheat to flour and eat it ourselves as bread, or whether we let the seed germinate, in which case the young plant eats it, the process is identically the same.

The power of storing up food in a fixed condition and utilising it when required is a most important function both in animal and plant physiology. And just as this utilisation is seen in the seed to be brought about by a ferment—by a digestive process—so probably wherever the transference or utilisation of food stores occurs it is effected by ferments. If this be so it would seem that the processes of digestion proper, as they occur in the stomach and intestines of animals and on the leaves of carnivorous plants, I say it is probable that these processes are only a specialisation[1] of a widely spread power, which may exist in the simplest protoplasmic ancestor of animals and plants. In this case we shall have no right to consider the existence of carnivorous plants anything strange or bizarre; we should not consider it, as seems sometimes to be done, an eccentric and unaccountable assumption of animal properties by plants; but rather the appearance of a function which we have quite as much right to expect in plants as in animals. Not that this view makes the fact of vegetable digestion any less wonderful, but rather more interesting as probably binding together by community of descent a wide class of physiological functions. Let us now pass on to consider the analogies of plants and animals in a more advanced stage of life.

---

[1] A Lecture delivered at the London Institution on March 11 by Francis Darwin, M.B.

[3] *Ann. Sc. Nat.*, 1873, xvii. p. 205.

Great differences exist among animals as to the degree of development attained before the young ones enter the world. A young kangaroo is born in a comparatively early stage of development, and is merely capable of passive existence in its mother's pouch, while a young calf or lamb soon leads an active existence. Or compare a human child which passes through so prolonged a condition of helplessness, with a young chicken which runs about and picks up grain directly it is out of its shell. As analogous cases among plants, we may take the mangrove and the tobacco plant. The ripe seed of the mangrove is not scattered abroad, but remains attached to the capsule still hanging on the mother plant. In this state the seeds germinate and the roots grow out and down to the sea-level, and the plant is not deserted by its mother until it has got well established in the mud. It is due to the young mangrove to say that the conditions of life against which it has to make a start are very hard on it. The most intrepid seedling might well cling to its parent on finding that it was expected to germinate on soft mud daily flooded by the tide. Perhaps the same excuse may be offered for the helplessness of babies—the more complicated the conditions of life, the greater dependence must there be of offspring on parent.

Now compare a young tobacco plant with the mangrove. All the help the seedling tobacco receives from its parent is a very small supply of food; this it uses up in forming its first pair of leaves; it has then nothing left by way of reserve, but must depend on its own exertions for subsistence. By its own exertions I mean its power of manufacturing starch (which is the great article of food required by plants) from the carbonic acid in the air. In this respect it is like a caterpillar which is formed from the contents of the egg, but has to get its own living as soon as it is born.

In many cases there is a certain degree of independence in young creatures, which are nevertheless largely dependent on their parents' help. Thus, young chickens, though able to feed themselves, depend on their mother for warmth and guidance. A somewhat parallel case may be found among plants. It has been shown that the large store of reserve material in a bean is not all needed for the development of the seedling. It has been proved that well-formed and flourishing seedlings are produced, even when a large part of the cotyledons has been removed. In fact, the store of food in the bean has been said to play a double part in the economy of the plant,[2] first, as giving absolutely necessary formative material, and secondly, as protecting the young plant in the struggle with other plants, by supplying it with food till it is well established and able to make its own food. This view was fully established by my father,[3] who sowed various kinds of seed among grass in order to observe the struggle; he found that peas and beans were able to make a vigorous start in growth, while many other young plants were killed off as soon as they germinated.

The young bean is thus indirectly protected by its mother from death, which the severe competition entails on less fortunate seedlings. This kind of protection can only in a certain general sense be compared with the protection given by parent to offspring. Nevertheless, a more strictly parallel case may be found among animals. Certain fishes retain the yolk bag, still containing a supply of food, and swim about leading an independent life, carrying this store with them. Among plants, a good case of a retention of a store of food occurs[4] in the oak. Young trees possessing woody stems and several leaves may still have an acorn underground with an unexhausted store of food.

In comparing the lives of plants and animals, one is struck with the different relation which the welfare of the race bears to the welfare of the individual. In plants it is far more obvious that the aim and object of existence is the perpetuation of the species. The striking and varied development of the reproductive organs in plants is one factor in this difference. Roughly speaking, plants strike us most by their flowers and seed—that is by organs serving the interest of the race. Animals are most striking on account of their movements, which are chiefly connected with the wants of the individual. If a child wants to know whether a stick *is* a stick or a caterpillar, he touches it, and if it walks off, classes it in the animal kingdom. Of course, I do not mean that the power of movement is a mark of distinction between animals and plants, but it certainly is a power which is well developed in most animals, and badly developed in most plants. It is the absence of locomotive powers (as opposed to the absence of simple movements) that especially characterises most plants. One sees the meaning of this if one inquires into mode of life of stationary and of locomotive animals. Stationary animals either inhabit the water, or else are parasitic in habits, and live on tissues of plants or animals. In either case the absence of locomotion has the same meaning. Many aquatic animals derive their food from the minute organic particles floating in the water, so that even though they lead a stationary life, food will be brought to them by the currents in the water. Parasitic animals obtain their food directly from the juices or sap of their host, so that they do not need to move about as other animals do in search of food. In the same way plants live like parasites on the earth, penetrating it with their roots, and sucking out its juices; and their food—carbonic acid—is brought to them by the currents of the air, so that like both an aquatic and a parasitic animal, they have no need of locomotion as far as concerns the obtaining of food.

In the case of many young animals their powers of locomotion would be useless unless the eggs were deposited by the mother in a proper place; one cannot imagine anything more forlorn than a caterpillar reared from an egg laid anywhere by chance, and expected to find its proper plant. The necessity of finding proper places to lay her eggs implies the necessity of locomotion on the part of the mother. This need of locomotion is, of course, equally a need to the plant, but it is supplied in a distributed way. The seeds themselves become locomotive; they either acquire plumes to fly on the wind like the seeds of dandelions or they become burrs and cling to passing animals, or are distributed in other ways. Various and strange are the means of transportal adopted by seeds; for instance, the acorn seems to distribute itself by deliberately trading on the carelessness of creatures which are usually considered its superiors in intelligence. Good evidence exists that young oaks which grow scattered in large number over a wide extent of wild heathy land have sprung from the acorns accidentally dropped by passing rooks. In all these cases the young plant has to trust to chance as to what kind of soil it will be deposited in, and this of course accounts for the enormous number of seeds produced by plants. Some seeds are more fortunate in possessing a kind of mechanical choice or power of selecting suitable places to grow in. Many years ago my father described a plumed seed which, when damped, poured out a sticky substance capable of gluing the seed firmly to whatever touched it. Imagine such a plant blown by the wind over some sandy waste; nothing tends to stay its course till it happens to pass by a region where the soil is damper; then it sends out its sticky anchors, and thus comes to rest just where it has a chance of germinating favourably. Again, some seeds have a certain amount of locomotive power independent of such external agencies as wind or passing animals. I mean a power of burying themselves in the ground; the seeds of grasses are the best known of these self-burying seeds; and among them the feather-grass, or *Stipa pennata*, is the most conspicuous. These seeds possess a strong, sharp point, armed with a plume or tuft of recurved hairs, which act like the barbs of an arrow and prevent the seed from coming out again when it has once penetrated the soil. This arrow-like point is fixed at the lower end of a strong awn, which has the remarkable property of twisting when dried and untwisting when wetted. Thus the mere alternations of damp nights and dry days cause the arrow-like point to rotate, and by another contrivance, which it would take too long to go into, the point is pressed against the surface of the ground and actually bores its way into it. Fritz Müller described in a letter to me how these twisting grass seeds bury themselves in the extremely hard and dry soil of Brazil, and are thus no doubt enabled to germinate. Unfortunately these boring grass-seeds do not always confine themselves to penetrating the soil, but exercise their powers on both men and animals. I have received accounts from India and from Italy of the way in which the sharp-pointed seeds work their way through thick trousers into the legs of unfortunate sportsmen. But the most extraordinary case is that of certain grasses which work their way into sheep. They often penetrate the skin deeply and in large numbers, inflicting great tortures and often causing death by emaciation. Mr. Hinde, of Toronto, has given me the details of this plague to sheep-farmers as it occurs in Buenos Ayres. Another observer has described it in Australia.[1] He states that not unfrequently the seeds are found actually piercing the heart, liver, and kidneys of sheep which have died from the effects. I believe that the northern part of Queensland has been actually given up as a sheep country because of the presence of this grass.

Another use to which locomotion is applied by animals is that of finding a mate at the proper season. The curious imitation of the courtship of animals which is found in Vallismeria is well known. The stalk grows with extreme rapidity up through the water till the female flower reaches the surface, and there awaits the approach of the male flower, which breaks loose and floats down the stream to meet her. But most plants have not even this amount of locomotive power, and are therefore compelled to employ either the wind or insects as go-betweens. Fortunately for the beauty and sweetness of our woods and fields, insect fertilisation is the commonest means adopted; and all the bright flowers and sweet smells of flowers are nothing but allurements held out to insects to entice them to carry the fertilising pollen from one flower to another. It is curious to find a plant adopting a new mode of conveying its pollen when the old one fails. Thus, a wild cabbage-like plant which grows in Kerguelen's Land is now fertilised by the wind, that is, it produces dry dust-like pollen, which is easily carried by the wind. Now this cabbage is the only species in the enormous order of the Cruciferæ which is not fertilised by insects; so that we may be certain that a change has taken place for which some sufficient reason must exist. And the reason of the change is no doubt that the insects in Kerguelen's Land are wingless, and are therefore bad distributors of pollen. And to go one step further back, the reason why the insects are wingless is to be found in the prevalent high winds. Those insects which attempt to fly get blown out to sea, and only those are preserved which are gradually giving up the habit of flying. Thus the pollen of the cabbage has to learn to fly, because the insects will not fly for it.

In considering the analogies between plants and animals, one cannot merely compare those functions which are strictly and physiologically similar in the two kingdoms. One rather sets to work and studies the needs which arise in either a plant or an animal, and then discovers in what way the same need is supplied in the other kingdom. There is no connection between a plant having bright flowers and an animal's power of walking about, yet they may, as we have seen, play the same part in the economy of the two lives.

In the life of animals the first needs that arise are supplied by certain instinctive movements. The young chicken only escapes from its egg by some such movements. Mr. W. Marshall has also shown that the chrysalides of certain moths possess instinctive movements by which they escape from the cocoon or outer case. In one case a sharp spike is developed, sticking out from the side of the chrysalis, and as the latter rotates the spike saws the cocoon all round, so that the top lifts off like a lid. Again, in young chickens Spalding has shown the existence of an instinctive power of obtaining food, and instinctive recognition of the hen by sound only. This was proved by a newly-hatched chicken, which had never heard or seen its mother, running towards a cask under which a clucking hen was hidden. The powers of growth which exist in young seedlings would certainly be called instinctive if they existed in animals, and they are quite as indispensable as those just mentioned in supplying the wants which first arise.

These two instincts are the power of directing the growth in relation to the force of gravity, and in relation to light; the first being called geotropism, the second heliotropism. As soon as the young root emerges from the seed-coats, it turns abruptly downwards, perceiving like the chick in what direction the earth, its mother, lies. Thus the young plant fixes itself firmly in the ground as quickly as possible, and is enabled to begin to make arrangements for its water supply. At the same time the young stem grows upwards, and thus raises itself as much as possible over its neighbours. The power of directing itself vertically upwards is also a necessity to the plant, because without it no massive growth like that of a tree would be possible. It would be like a child trying to build a wooden house with bricks that did not stand straight. Thus, both the young stem and the young root have an instinctive knowledge as to where the centre of the earth is—one growing towards the point, the other directly away from it. This fact is so familiar to us, that we fail to think of it as wonderful; it seems a matter of course, like a stone falling or a cork floating on water. Yet we cannot even generalise the fact so far as to say it is the nature of all stems to grow up, and all roots to grow down, for some stems, such as the runner of a strawberry, have a strong wish to grow down instead of up, and side roots that spring from the main ones, though their method of growth is identical with that of the main roots, have no wish to grow downwards. We can find no structural reason at all why a root should grow down and a stem up. But we can see that if a plant took to burying its leaves and rearing its roots into the air, it would have a bad chance in the struggle for life. It is, in fact, the needs of existence which have impressed these modes of growth on the different organs of the plant in accordance with their various requirements. On the other hand, the plant is not absolutely tied down by geotropism, it is not bound to grow *always* in a vertical line, but is ready to be turned from its course if some other direction can be shown to be more advantageous. Thus Sachs[1] planted peas in a little sieve, and as the roots emerged underneath, they were enticed from the vertical by an oblique damp surface. This power of giving up the line of growth for the sake of a more advantageous position, must be of great service to roots, by enabling them to choose out damp places in the earth which a blind adherence to rule would have caused them to pass by.

The other tendency, which may be also compared to an instinct, is the power possessed by the growing parts of plants of perceiving the position of the chief source of light. This tendency of course interferes with the geotropic tendency, for if the tip of a growing shoot bends towards the light it deviates from its vertical course. This contest between two instincts is well shown by placing a pot of seedlings close to a lamp or a window, in which case the heliotropic beats the geotropic tendency and the young plants curve strongly to the light; now if the pot is removed to a dark room the geotropic tendency reasserts itself, and the seedlings become once more upright. One might fancy from this that the darkness of night would be always undoing any good gained by heliotropic growth in the day. An imaginary case in the life of a seedling will show that it is not so. A seedling germinates under a pile of sticks: having few competitors it makes a good start, but in consequence of the darkness it begins to starve as soon as it has exhausted the supply of food given it by its mother plant stored up in the seed from which it sprang. It starves because it is dark under the pile of sticks, and without light it cannot decompose the carbonic acid of the air and make starch; carbonic acid may be said to be the raw material from which a plant makes its food—but without the help of light the plant is powerless to make food—it starves in the midst of plenty. So that the power of knowing where the light is and of moving towards it may be just as necessary to prevent a young plant starving as the power of knowing a grain of corn when it sees one and of snapping it up are to a young chicken. Luckily for our imaginary plant a ray of light streams in between two sticks—if the plant insisted on growing straight up in obedience to the geotropic instinct it would lose its chance of life. Fortunately the other light-seeking instinct wins the day and the plant thrusts its summit between the sticks and reaches the light. And now it is clear that when the plant has once got between the sticks the tendency to straighten again in the night will not be able to undo the advantage gained in the day by heliotropism. Besides the tendency to seek the light, there is in some plants another exactly opposite tendency to grow away from it. Just as in the case of geotropism no reason can be given why two organs should be affected in exactly an opposite manner by the same cause; no difference of structure can be perceived and no difference in manner of growth can be found between a tendril which grows away from the light and one which grows towards it. The convenience of the plant seems to dictate the result. Thus th[illegible]ginian creeper climbs by forming little sticky feet at the end of its tendrils, and as it climbs up a support each new tendril is enabled by its power of seeking for darkness rather than light to find out little dark crannies in which to place its feet. On the other hand a bryony climbs by seizing anything it can get hold of, and as each tendril reaches out towards the light the whole plant will tend to be dragged towards the lighter side of the bush or hedge on which it clambers.

[1] C. Prentice, *Journal of Botany*, 1872, p. 22.

[1] "Text Book of Botany," Eng. Tr. p. 764.

It looks as if the case might be put thus: Given the fact that light produces some kind of movement, the convenience of the plant shall decide whether it be towards the light or away from it; or in other words, grant the plant the power of knowing where the centre of the earth is, and grant it the power of knowing where the light comes from, then the plant itself can decide what course of growth is most advantageous.[1]

(*To be continued.*)

NOTES

THE subscription for M. Leverrier's statue is progressing favourably. A sum of 4,200 francs has been already collected. The subscribers up to the present moment number thirty-five, almost all of them belonging to the French Institute. M. Cohen, of Antwerp, sent 1,000 francs. Other large sums are expected soon from different parts.

IT is stated that M. Faye has declined to stand for the direction of the Paris Observatory, unless it is agreed to retain at the observatory the International Meteorological Office. It is very probable that the long spoken of Meteorological Institute will now be established; at all events a solution of the pending question will soon be adopted by the government.

M. DUMAS announced to the Paris Academy of Sciences at its sitting on March 4 that an anonymous donor offers a prize of 6,000 francs to be awarded in 1880 to the person who makes the most useful application of M. Pasteur's researches to the [illegible]

[illegible] has been formed at Königsberg to erect a [illegible] on the grave of the great philosopher Im- [illegible] The City authorities have leased the lot of [illegible] sum of 4,000 marks (2 [illegible]

IN a report by M. Daubrée to the Paris Ac[illegible] it is strongly recommended that measures should be taken to preserve the many boulders which are scattered over France, and many of which are disappearing under the [illegible] of the builder. The Academy has appointed a commission for the purpose, which will have delegates in the principal parts of the country. Similar measures have been taken in Switzerland since 1866, and our Scotch geologists deserve praise for their zeal on behalf of the preservation of the boulders of their country, and for their excellent periodical reports on the subject.

GEN. DUFF, in a letter to the Earl of Derby, dated Gothenburg, January 4, reports that great shoals of herrings of the large kind which disappeared from this coast in the year 1809 have now made their appearance again north of Gothenburg. The first appearance of the herring took place at Christmas, when whales were seen following the shoals toward the coast. Preparations were made by the merchants of Gothenburg to make good use of this godsend. It would appear from the history and traditions of Sweden that, after an interval of seventy years, there are some grounds for supposing that the shoals of herrings may be expected to visit the coast regularly for fifty or sixty years to come, as has been the case during earlier periods. The Swedish Government have appointed Professors Sars and Smitt to inquire into the various questions raised by this sudden appearance of the herring shoals off this part of the Swedish coast, the more important of these questions being the alleged disappearance of the shoals from the coast of Norway, whither, it is said, they have betaken themselves since 1808, and the bearing of the inquiry on the future of the fishery.

THE first National Entomological Exhibition commenced on Thursday at the Royal Aquarium, Westminster, and is thoroughly creditable to all concerned. There are altogether about 250 exhibitors contributing between eight and nine hundred cases, with an average of at least 300 insects per case; and the whole of the specimens shown, with very few exceptions, have been collected by ladies and gentlemen and artisans, in their leisure hours.

WE regret to learn the death of Joachim Monteiro, at Delagoa Bay. He was an active and enterprising naturalist, whose work on Angola will give him an enduring place in the literature of African travel, no less than his services in procuring and sending to this country a great part of the fine series of specimens from which *Welwitschia* was originally described.

THE death is announced of Sulpiz Kurz, the Curator of the Herbarium of the Calcutta Botanic Garden. Possessed of an extensive knowledge of Indian botany, he had recently completed the preparation of a Flora of British Burma for the Indian Forest Department. He died at Penang on his way to the islands of the Malayan Archipelago, for the purpose of botanical exploration.

A LETTER has been written by the Municipal Council of Paris to the director of the Meteorological Service of the Observatory asking that the publication of weather telegrams and prognostications be made in Paris as well as in provincial towns.

A GREAT prehistoric burial ground has recently been discovered at Cremmen (in the district of East-Havelland, Prussia), not far from Berlin. Numerous urns and ash jars of varied form, all containing ashes and bones of burnt human remains, have been found. The urns are mostly round in shape, and stood some 2½ to 3 feet below the surface upon a large slab of stone; they were surrounded by round stones, and each was covered with a flat stone lid. The antiquities will all be deposited in the Provincial Museum of Berlin.

AN International Agricultural Exhibition will take place at Hamburg on June 13, and will last 5 days; and another exhibition of this nature will be held at Prague on May 15, 16, and 17.

THE Royal Society for Agriculture and Botany of Ghent, will hold its Horticultural International Exhibition on March 31 next. These exhibitions are quinquennial, and last for seven days. The coming one promises to be unusually brilliant, to judge from the copious list of names of exhibitors.

WE are glad to see that a beginning has been made in the formation of a local museum at Tenby, the proposal for which we referred to some time since. The magnificent geological collection of the late Mr. Smith, of Gumfreston, has been purchased. The Corporation of Tenby has given the old National School-rooms on the Castle Hill, and after some slight alterations have been made they will be admirably well adapted for a museum. In addition to the geological specimens there will be a valuable collection of British shells, and one of Pembrokeshire birds and eggs; also a library of scientific books. It would be idle to speak of the advantage this institution is likely to confer on the town, and on all the residents in South-west Wales, where nothing worthy of the name of a museum at present exists. About 300*l.* is still required before the museum can be opened. The trustees ought to have no difficulty in raising this moderate sum in the district concerned; perhaps some of our readers might like to contribute. The hon. secretary is Mr. Edward Laws, Tenby.

---

[1] I have spoken as if the existence of positive and negative helio- and geotropism could be simply explained by considering the convenience of the plant. But in details many difficulties arise, for instance, some roots are heliotropic (Sachs' "Text Book," p. 755.)

THE *Spectator* learns from a private letter that the telephone has been adopted by the Chinese, the telegraph being useless, as they have no alphabet. Five hundred miles, it is stated, have already been spoken over in China. Mr. H. F. Stevens writes from Tabreez, Persia, that conversation and music were transmitted satisfactorily by telephone between that town and Tiflis, along the line of the Indo-European Telegraph Company.

AT a recent meeting of the East Kent Natural History Society, Prof. Gulliver exhibited a very extensive series of drawings of raphides and other crystals found in the tissues of plants. Mr. Gulliver considers that sufficient attention has not hitherto been directed to the part played by these deposits of mineral salts in the vital economy of the plant, or, from the soluble condition in which they are presented, in the nutrition of the animals which feed on them.

Apropos of the note in NATURE (vol. xvii. p. 311) relating to a recent attempt to send certain fish to America, Mr. Carrington, of the Westminster Aquarium, writes that there are in the Royal Aquarium, Westminster, at least eighteen species of fish from American waters. In return he has exported a number of sea-water animals, including fish, molluscs, crustaceans, and zoophytes. At first a large proportion of specimens was lost during the voyage, but now there are seldom any lost, either on the homeward or outward voyages. In addition to the constant attention necessary at sea, Mr. Carrington finds the great secret of success is to have the animals subjected to confinement for some weeks before shipment.

MESSRS. LONGMAN have published an abridged edition of Dr. Pole's excellent "Life of Sir W. Fairbairn." The personal narrative has been retained entire, the scientific and technical portions being much abridged. The little work deserves, and no doubt will have, a wide circulation.

WE are pleased to see that the *Natural History Journal*, conducted by the Societies in Friends' Schools, whose appearance we noted a year ago, has reached the beginning of a second volume. Of the 170 contributors sixty-three, we learn, have been boys and girls. The journal is well conducted and, judging from the number before us, its contents are well calculated to interest its young readers in science.

IN NATURE, vol. xii. p. 514, W. W. Wood, writing from Manila, describes a species of Navicula (?) with a gelatinous ciliated envelope, which is there figured. Mr. Wood announced his intention of submitting his specimens to a competent diatomist, but three years have nearly elapsed, and no more has been said on the subject. It is one of such extreme importance as bearing on the ordinary motion of diatoms, that Mr. G. S. Boulger writes asking for an explanation.

MANY of our readers will be sorry to hear of the death, on Monday last, of the old hippopotamus, in the Gardens of the Zoological Society. He was obtained in the White Nile when only a few days old, in 1849, and has been in the Gardens since 1850. Prof. Garrod, F.R.S., will communicate the results of his examination of the body to an early meeting of the Zoological Society.

WITH reference to a note in NATURE (vol. xvii. p. 38) respecting the uninflammability of eucalyptus, Mr. A. Nicols writes that this must be a mistake, as in Australia the wood is extensively used as fuel. Acclimatisation of these really valuable trees, Mr. Nicols thinks, should be strongly supported. They yield timber of immense size and strength, durable alike in dry or wet situations, and more proof against the attacks of *termites* than many other woods, and some work up into beautiful furniture. They would probably thrive wherever the mean annual temperature is not below 60°, or, roughly speaking, over an area of about one-half of the habitable region of the earth.

THE provisional observatory at Meudon is in full operation, as we reported some months ago. Dr. Janssen has done such good work that the ministry will propose to restore the old palace which is now in ruins, and establish a splendid physical observatory in an admirable situation. A credit of 250,000 francs is to be asked for; this will include the purchase of a refractor 0m. 67 in. diameter.

THE governor of the French island, Reunion, in the Indian Ocean, reports that this colony was visited by a terrible cyclone on January 15, causing great losses of life and property.

UNDER the auspices of the Deutscher Fischerei-Verein, 2,000,000 salmon eggs are hatched annually, and distributed among the various rivers of the empire. Strong efforts are now being made to introduce extensively the grayling, which is comparatively rare in Germany.

IN the February session of the Berliner polytechnische Gesellschaft, Dr. F. Siemens, of Dresden, the inventor of the new compressed hard glass, gave an interesting exhibition of this new invention. The process has been brought to such perfection, that the hard glass is not only more easily, but more cheaply manufactured than the ordinary glass. The power of resistance varies from eight to ten times that of ordinary glass. The serious objection made to hard glass at the time of its discovery, that it often fell to pieces when entirely unexposed to pressure, has been successfully avoided. This property was found to result from over-hardening, and it is now possible to detect all articles which have acquired it, by the use of the polarisator, under which over-hardened glass shows a prevalence of violet tints. This condition is also detected by exposure to water at a certain temperature.

THE working out of the results obtained by the Transit of Venus expeditions sent out by the German Government, were expected to have been far enough advanced for publication in the year 1877. It has been found, however, that this task causes more difficulties and expenses than had been at first anticipated. The Imperial Chancellor's office has therefore demanded from the German Parliament an extra credit of 500*l.* to defray the additional costs.

A USEFUL invention has recently been made by Herr Weber, of Hummel-Radeck, near L[illegible]ben (Prussia). This gentleman has contrived to construct a very simple machine for levelling roads, which for working requires only two horses, a driver, and a labourer, and renders it possible to make such improvements in a road, in a short time as could otherwise be accomplished only by fifty or sixty workmen. The machine works equally well upon gravel or clay soil, and its cost is only forty-five marks (shillings). The whole machine works much in the same way as an ordinary carpenter's plane does upon wood.

ON January 25, shortly after noon, the belfry of Toucy (Yonne) was struck by lightning, and set on fire. According to Dr. Roche (who describes the case), the wind was blowing from the north-west, and a dense, low cloud had begun to cover the ground with large hailstones. A few minutes after a single and prolonged thunder peal was heard, and the cross on the belfry was then seen to be surrounded by a luminous meteor. Persons in the houses near the church saw coming from the base of the belfry two fire-balls of about 0·30m. to 0·40m. diameter, and about 0·50m. apart. They rolled on the steps of the building about 20m. and disappeared. A woman in a room about 15m. from the belfry was carried to the end of the room; a young man who was passing was thrown on the ground, and several other persons were more or less shaken. Immediately after the thunder peal the hail ceased and was replaced by a snow-storm which lasted three-quarters of an hour. It was afterwards found that the belfry was fired at two points—one at the upper part of the north-west side, the other at the lower part of the south-east side, probably the points of entrance and exit of the electric fluid. Toucy stands in the middle of a narrow valley, running north-west, and is rarely visited by thunderstorms, which pass nearly always to the right or left.

SOME researches on the magnetic properties of nickel were recently made by the well-known physicist M. H. Wild, and are now published in the *Bulletin* of the Imperial Academy of Sciences of St. Petersburg. M. Wild arrives at the following conclusions: (1) Pure nickel can become permanently magnetic to a considerable degree, thus differing materially from pure (soft) iron. The maximum quantity of permanent magnetism which pure nickel can retain is, however, only between one half and one-third of that quantity which hard steel can permanently retain. (2) Magnetism is less permanent in nickel than in well-hardened steel, after the magnetising force has ceased to act; the slow loss of magnetism in course of time, as well as by heating and cooling, is comparatively greater in nickel than in steel; and this is the case even if the nickel has, like hard steel, by repeated heating and cooling, been brought to a certain state of permanent capacity. (3) The temperature coefficient of nickel magnets in the latter state is a little larger than that of properly hardened steel. (4) The temporary magnetism which pure nickel can retain is about double its permanent quantity, or about one half of the temporary magnetism which hard steel, and about one quarter of that which soft iron can retain. In its magnetic properties nickel is, therefore, thoroughly inferior to iron and steel.

THE question with regard to the existence of microscopic organisms in media containing no oxygen has been a fruitful subject of discussion for biologists of late, and some doubts have been thrown on the entire absence of this gas in the experiments cited by Pasteur and others. Prof. von Nägeli, in his work on "Die niederen Pilze," which has just appeared in Munich, presents some interesting figures in this connection. According to his calculations the larger bacteria weigh [illegible] milligramme. If we assume that they consume the same amount proportionally of oxygen daily as a man, viz., 1 per cent. of his weight, then a million bacteria would require in twenty-four hours [illegible] milligramme, or nearly [illegible] cubic centimetre of oxygen. These calculations, taken in connection with the well-known difficulties of entirely eliminating gases, will probably render a repetition of the best experiments necessary.

FROM recent experiments on the spread of gases through bodies, Dr. Wroblewsky (*Pogg. Ann.*) arrives at the following conclusion:—"When a gas is absorbed it spreads in the absorbent body according to the same laws as those ruling the propagation of heat in a solid bar; and that whether the absorbent body be liquid or solid, or in a transition state between these two extremes." The only exceptions to this law are attributable to the action of gravity. It is known that the excretion of carbonic acid by an animal is increased by a violent muscular action, but it has been uncertain whether the CO_2 is a direct product of muscular action, *i.e.*, belongs to the substances which, through decomposition processes, are formed in greater measure during contraction of the muscles. To clear up this point, M. Sedgwick-Minot recently forced through the vascular system of detached muscles of dogs (the blood having been removed) a quantity of blood-serum saturated with oxygen, and determined the proportion of CO_2 in the serum in a series of cases in which the muscles were at rest, and in another series in which they were repeatedly stimulated to contraction. If the contraction of the muscle caused a greater formation of CO_2, the serum, after passage, must contain more CO_2 than if the muscle remained at rest. The experiments, however, gave equal quantities of CO_2 in the two cases, and the reason of the fact referred to at the outset is not determined.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus*) from India, presented respectively by Capt. Pole Carew, and Mr. Henry Wright; a Green Monkey (*Cercopithecus callitrichus*), two Common Chameleons (*Chamæleon vulgaris*) from West Africa, presented by Mr. G. H. Garrett; a Herring Gull (*Larus argentatus*), European, presented by Mr. Capstick; two Undulated Grass Parrakeets (*Melopsittacus undulatus*) from Australia, presented by Mr. Hylton Jolliffe; an American Darter (*Plotus anhinga*) from South America, purchased; two Sambur Deer (*Cervus aristotelis*), an Isabelline Bear (*Ursus isabellinus*) from India, a Javan Adjutant (*Leptoptilus javanicus*) from Java, received in exchange.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—Mr. J. R. Terry, M.A., Fellow of Magdalen College, who was Fifth Wrangler at Cambridge in 1873, has accepted the senior mathematical mastership in Magdalen College School; and Mr. D. C. Robb, B.A., scholar of Worcester College, has been appointed to a science mastership (in physics) at the same time.

CAMBRIDGE.—The report of the Council of the Senate recommending the appointment of an assistant to Prof. Hughes has been confirmed upon the understanding that the person to be appointed be not permitted to take private pupils.

EDINBURGH.—A movement has originated in the University of Edinburgh to procure a portrait of Prof. Balfour, in recognition of his services to the University in having for thirty years acted as Dean of the Medical Faculty. This movement has been joined in by the Fellows of the Royal Society of Edinburgh, in recognition on their part of the services he has for many years rendered to the Society in the character of Secretary.

BIRKBECK INSTITUTION.—A course of six lectures on Electric Telephony will be delivered by Mr. W. J. Wilson, F.C.S., on Saturday evenings, at eight o'clock, commencing March 23. The entire proceeds will be given to the fund now being raised for the erection of a new building for the institution. The lectures will be very fully illustrated by experiments, diagrams, &c., and will form a complete exposition of the subject.

PARIS.—M. Pierre Picard is proposed as a successor to the late Claude Bernard in the chair of physiology at the Collége de France. He was for a long time assistant to the famous physiologist, and is himself the author of valuable researches on the constitution of the blood corpuscles. At present he is a professor in the Faculty of Medicine at Lyons.

ALGERIA.—M. Bardoux proposes to establish in Algeria three preparatory schools for medical and law students, one in each of the three provinces. At present Algiers alone is provided with a preparatory school of medicine. The means for obtaining superior instruction, which have been very limited up to the present in the colony, will be greatly enlarged.

BERLIN.—On the night of the 8th instant the professors and students of the Berlin University, assisted by civil and military dignitaries, held a grand "Commers," or beer-drinking revelry, in the time-honoured style of German academical life, in honour of the sixtieth anniversary of the birthday of Prof. A. Hofmann, the celebrated chemist. The proceedings began by the secretary of the committee reading a letter from the Chamberlain of the Crown Prince expressing the regret of his Imperial Highness at being prevented from attending the festivity. After this Prof. Helmholtz, the Rector of the Berlin University, formally congratulated Dr. Hofmann, who replied in a speech to the felicitations addressed to him by his Berlin colleagues and friends. Numerous other speakers, among them Privy-Councillor Jacob, Chief of the Patent Office, and Prof. Reuleaux, Rector of the Berlin Polytechnic Academy, then addressed the hero of the day. The official part of the festivity closed at 2 o'clock, after which came the singing of all the obligatory songs and the delivery of student speeches. Not a few congratulatory letters and telegrams reached Prof. Hofmann on the auspicious day from England, America, and France.

PRUSSIA.—The three agricultural institutes of Prussia are attended at present by 270 students, of whom 215 are from Prussia, 20 from other parts of Germany, and 35 from foreign countries.

GERMAN POLYTECHNIC CONGRESS.—At the recent inauguration of the new Polytechnic Institution of Brunswick, the assembled men of science considered the question of a general congress of lecturers at the German polytechnic schools. It is intended to hold the congress at Dresden, and a preliminary meeting of delegates will take place in the beginning of April, in order to fix the programme for the congress. Dresden has also been selected as the meeting-place for a congress of German engineers and architects, and it is supposed that the two meetings will be held simultaneously.

SAXONY.—An interesting example of the comparative sums devoted in Germany to various educational purposes is to be seen in the recently-issued Report of the Minister of Public Instruction for Saxony, a kingdom with 2,550,000 inhabitants. The whole number of educational establishments is 3,900, of scholars and students, 523,000, of instructors, 6,400. The salaries amount to 12,300,000 marks, and the total educational expenses are 18,000,000, of which 5,000,000 are contributed by the Government. The State devotes 766,000 marks to its 76 gymnasia and *Realschulen*, 1,354,000 to the general school system, and nearly as much, viz., 1,048,000 marks to the University of Leipzig with its 161 professors and 3,100 students, besides 893,000 marks for pensions. The total annual cost of the Leipzig University is 1,402,000 marks, or 70,100*l.*

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 1, 1878.—The universal compensator, by M. Beetz.—On the electromotive force and the internal resistance of some thermopiles, by M. Beetz.—The theory of stationary currents regarded from a quite general standpoint, by M. v. Bezold.—On a tangent multiplier and the electromotive force of the Grove element, by M. Riecke.—On the influence of density of a body on the amount of light absorbed by it, by M. Glan.—On the theory of the longitudinal-elliptical vibrations in the incompressible ether, by M. Ketteler.—On fluorescence, by M. Lommel.—On metallic reflection, by M. Wernicke.—On the volume-increase of liquids through absorption of gases, by Messrs. MacKenzie and Nichols.—Some observations on Crookes's radiometer, by M. Riecke.—Determination of the resonance-tones of the mouth-cavity by percussion, by M. Auerbach.—On the pitch of a tuning-fork in an incompressible liquid, by M. Auerbach.

Zeitschrift fur wissenschaftliche Zoologie, vol. xxx., part 1.—Rhizopod studies, by Emil Buck, 49 pp. 2 plates; dealing with the development of arcella, and a new genus parasitic on rotifers.—Revision of the genus analges (avian parasite), by G. Haller.—Contribution to the anatomy of asteridæ, by Hubert Ludwig, 4 plates, 63 pp., describing the water-vascular system, the blood system, the nervous and the generative apparatus, the body cavity.—Contribution to the natural history of the cestodes, by H. A. Pagenstecher, dealing with *Tænia critica* and *Cœnurus serialis.*

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, February 21.—W. Carruthers, F.R.S., vice-president, in the chair.—Mr. Thos. Christy illustrated by diagram and made remarks on M. Ossenkop's new system of plant-propagation; and he also showed the recently imported fresh berries of the Liberian coffee of this year's crop.—Mr. Holmes exhibited a remarkable oak gall of *Aphilothrix sieboldii*, Hart., obtained at Willesboro, Leas, Ashford.—Mr. Thiselton Dyer likewise exhibited and made a few observations on the inflorescence and a drawing of the palm *Ptychosperma rupicola*, Thw., which had flowered for the first time in Europe at Kew.—A paper, notes on the Mahwa tree (*Bassia latifolia*), was read by Mr. E. Lockwood. This tree grows in abundance in India; a hundred thousand may be seen in the plains around Monghyr. Wild animals of all kinds greedily devour the flowers, of which one tree will yield several hundredweights. Besides being highly nutritious to man, it is an excellent fattening agent for cattle, &c. A strong-smelling spirit is obtained by distillation of the corolla, an essential oil from the fruit, and as an agent in soap-making the tree is invaluable. Thus, certain yield, unlimited supply, nourishing and chemical qualities, easy preservation, and its cheapness, all combine to render it a commercial product of no mean importance to our Indian empire.—The gist of a "Synopsis of the Hypoxidaceæ," by Mr. J. G. Baker, was given. This group differs in some respects from the Amaryllidaceæ, and offers a close alliance with the Bellosiceæ. Four genera, and between sixty and seventy species are known. The Cape is their head-quarters, but some are found in Tropical Africa and Angola, a very few in Abyssinia and the Mascarenes. None are found in Europe, Polynesia, North and Central Asia, nor Extra Tropical South America.—The Secretary read an abstract of a technical paper on the Schoepfieæ and Cervantesiiæ, distinct tribes of the Styraceæ, by John Miers, F.R.S.—Then followed a communication by Mr. Arthur G. Butler, on the butterflies in the collection of the British Museum, hitherto referred to the genus Euplœa of Fabricius.—Dr. Hance, of China, Mr. E. Milner, Dr. Geo. Shearer, and the Rev. R. Boog Watson were elected Fellows of the Society.

Chemical Society, February 21.—Dr. Gladstone, president, in the chair.—A lecture entitled "Laboratory Experiences on board the *Challenger*" was delivered by Mr. J. Y. Buchanan. After describing his laboratory, which measured 10 feet by 5 feet 8 inches and 6 feet high, and its fittings, the lecturer gave a detailed account of the means by which, after estimating the compressibilities of water and mercury, he was enabled to determine the depths and temperatures attained by the sounding line. The compressibility of distilled water was found to be 0·000049 per atmosphere, or 0·0009 per 100 fathoms; of sea-water, 0·00077 per 100 fathoms; and of mercury, 0·0000271 per 100 fathoms, or 0·0000015 per atmosphere. He then described the apparatus and methods by means of which the amounts of oxygen, nitrogen, and carbonic acid were determined. The most interesting results obtained were the following:—From the surface down to 300 fathoms the amount of oxygen continuously decreases; from 300 fathoms downwards, whatever be the depth, the amount increases. This anomalous result the lecturer stated to be due to the great abundance of animal life at the depth of 300 fathoms, the increase in the quantity of oxygen at greater depths being caused by its non-consumption, owing to the scarcity of life. The next part of the lecture dealt with the distribution of the sea-water as regards density, in depth and superficially. Two regions of maximum density exist north and south of the equator, corresponding to the tracts frequented by the trade winds. At 350 fathoms deep a great zone of water of low density is found. The densest water is found in the Atlantic. Light water is found in the neighbourhood of ice and in certain regions immediately after the cessation of the monsoons. The maxima of density lie in the north hemisphere to the south-west, in the south to the north-west of the maxima of barometric pressure. A hearty and unanimous vote of thanks was given to Mr. Buchanan for his interesting lecture, which was illustrated by many tables and diagrams.

Physical Society, February 16.—Prof. W. G. Adams, president, in the chair.—The following candidate was elected a Member of the Society: Mr. G. H. West, M.A.—Dr. Lodge read, for Mr. H. F. Morley, M.A., a paper on Grove's gas battery. After referring to the views of M. Gaugain and Mr. Grove himself with regard to the cause of the action of this apparatus, the author proceeded to describe an elaborate series of experiments he has recently made in order to ascertain the circumstances by which it is regulated. It would be impossible to give a clear account of them in a short space, but some of his conclusions are as follows:—The whole of the current is due to dissolved gas, and if n be the distance of the level of the liquid from the top of the plate in the H tube, and $E = \frac{C\,R}{1{,}000}$, C being given in galvanometric readings and R in ohms, he finds that, approximately, $(1 + na)\,C = b + ne\ \ (c + nd)\,E$, where a, b, c, d, and e are constants. The electromotive force is not constant, but rises with the resistance. The current is greater in proportion as the gas present in the elements is less; and, finally, the current appears to vary directly with the pressure.—Mr. S. C. Tisley then described the harmonograph, specially referring to its use for drawing pairs of curves for the stereoscope. This, the latest forms of his pendulum apparatus, is capable of giving a very great variety of curves, for, in addition to rectangular vibrations, parallel and elliptic motions can be combined by its means. In the older form of apparatus each pendulum moves on the other as a centre, whereas in the instrument described they are independent. One pendulum carries at its upper end a table which can be caused to rotate by clockwork if required. The whole is supported on a kind of gimbal joint formed of two pairs of knife edges at right angles, so arranged that vibration can take place either on one or the other, or the two can be so combined as to give a circular motion; or again, the pendulum can be caused to vibrate in any given plane. The second pendulum vibrates in the plane in which the two hang, and carries at its upper end an arm terminating in a pencil over the table of the other pendulum. A very ingenious adjustment renders it possible to raise or lower the bob of the second-named pendulum during its motion. If two pens be attached, about 2½ inches apart, instead of the single one usually employed, and two curves be traced, they are not precisely similar, and when viewed in a stereoscope they are found to give the well-known appearance of solidity to the figure. It was further shown that by gradually changing the relative motions of the pendulums it is possible to impart to the curve many of the forms observed in biaxial crystals in the polariscope.—Mr. F. J. M. Page then exhibited the action of the telephone on a capillary electrometer. The construction of Lippman's electrometer as modified by Marey was first explained, and the meniscus of the mercury in the capillary tube was thrown on the screen by the electric light. The delicacy of the instrument was shown by passing a current of $\frac{1}{1000}$th of a Daniell, which caused a distinct movement of the mercury. Resistance of 5,000 ohms and $\frac{1}{10}$th ohm gave approximately the same deflection; so that, in practice, the instrument may be considered to be independent of resistance, in addition to which it possesses the great advantage of portability, and its indications are almost instantaneous. To illustrate the use of the electrometer for physiological investigations, a frog's heart was connected by non-polarisable electrodes with the instrument; each beat of the heart caused a considerable movement of the mercury column. A telephone was now connected; on pressing in the iron plate the mercury moved, and on reversing the wires the movement was seen to be in the opposite direction. On singing to the telephone each note produced a movement, but the fundamental note of the plate as well as its octaves and fifths had the greatest effect. On speaking the mercury oscillated continually; some letters of the alphabet had scarcely any effect, and the *w* was especially curious, producing a double movement. Reversing the wires did not alter the character or *direction* of these movements. The same effect was observed when the telephone was in the primary and the electrometer in the secondary coil of a Du Bois Reymond's induction coil. In conclusion, Mr. Page showed the contractions produced in a frog's leg; on inserting under the sciatic nerve two platinum wires coupled with the binding screws of a telephone and talking to this instrument, violent contractions ensued. In the course of the discussion which followed, Prof. Graham Bell expressed himself as highly gratified at the results of Mr. Page's experiments. He has made very many attempts to ascertain the strength of the current produced by the human voice in vain, but considers the present method will in all probability give some most valuable results. He was quite unable to account for the fact that the motion of the mercury took place *from* the opening, but this seems to depend on conditions not yet determined.—Mr. Wilson then exhibited, for Prof. S. P. Thompson, a lantern slide galvanometer for showing the deflections of the needle to an audience. It consists of a coil of insulated copper wire wound on a flat bobbin, within which a needle is balanced on a horizontal axis; this needle carries a long needle of aluminium traversing a semicircular divided photographic scale, and as this is transparent the index can be projected on to the screen. The whole is inclosed between two glass plates.

Geological Society, February 20.—Henry Clifton Sorby, F.R.S., president, in the chair.—James W. Carrall, Tientsin, China, Edward Cleminshaw, Percy John Neate, Arthur Nicols, John Snell, and John Spencer were elected Fellows of the Society.—The following communications were read:—Notes on the physical geology of the Upper Punjáb, by A. B. Wynne, F.G.S. The author stated that crystalline rocks are rare in the accession parts of the Upper Punjáb district, and that when present they consist of syenite and gneiss. The Cambrian and Silurian formations are represented by more or less metamorphosed azoic slates in the Himalayan district, and in the Salt Range by a zone less than 200 feet thick, containing either *Obolus* or *Siphonotreta*, underlain by a thick unfossiliferous sandstone, beneath which is a deposit of gypseous marl and salt. Above the Silurian in the Salt Range, and conformable to it, comes the magnesian sandstone group and a group of unfossiliferous sandstones and clays; in the Himalaya these deposits are probably represented by an unfossiliferous siliceous dolomite, which rests unconformably upon the slates. There are no fossils indicative of rocks of Devonian age. The carboniferous rocks, are also conformably deposited, on limestones, sandstones, and shales, the last sometimes carbonaceous. These deposits contain hæmatite in sockets, and the oldest known ammonites have been found in them. An infra-triassic group occurring in Lei Bau mountain consists of red shales, sandstones, and red quartzitic dolomites, overlain by lighter-coloured siliceous dolomites, which in their turn are covered by hæmatite, quartz breccia, sandstones, and shales. The author believes these to have been deposited by the same waters which subsequently laid down the trias, which is largely composed of limestones in the northern Himalayan area, and here and elsewhere includes dolomites, shales, and sandstanes. Numerous fossils occur in some of the beds, such as *Dicerocardium*, *Megalodon*, and *Nerinæa*. In the western part of the Salt Range conglomerates composed of great blocks are regarded by the author as evidence of proximity of land. The Jurassic deposits are local in their distribution, and consist of shales, sandstones, and limestones, containing abundant fossils, such as belemnites, ammonites, and saurians. A dark limestone contains also *Gryphæa* and *Trigonia*. The cretaceous deposits, when present, are conformable to the carboniferous; they are variable in thickness and fossil contents, and are not recognisable near Attock between the Jurassic and nummulitic groups. Further east a group, supposed to be cretaceous, includes clays with boulders of crystalline rock, which the author regards as derived from land to the south. One of these boulders presented glacial striæ. The eocene rocks are generally limestones, and lie conformably upon the subjacent formations. The nummulitic series of the Salt Range includes gypseous and coaly shales. The salt beds sometimes attain a thickness of over 1,000 feet. The Miocene and Pliocene deposits are of immense thickness, and contain only fossils of terrestrial and fresh-water origin, so that the deposits were formed in lakes and inland seas. The tertiary epoch closed with the elevation of the Himalayas and Salt Range, which was followed by a long period of change, during which various deposits were produced, some including great quantities of erratics, which, however, the author believes were brought to their present position rather by floating ice than by the extension of glaciers. Description and correlation of the Bournemouth beds; Part I., Upper or Marine Series, by J. Starkie Gardner, F.G.S. The author comes to the conclusion that the whole group is contemporaneous with the Bracklesham beds, and is not of Lower Bagshot age. Similar shore conditions probably extended into the London basin, and the beds mapped by the Survey as Lower Bagshot are probably of the same age as those at Boscombe, in which case nothing more than the Bracklesham is to be met with in the London basin. The similarity of the leaves, &c., from Bovey Tracey to those obtained by the author leads him to infer that the former also are of eocene, and not of miocene age. The author increases the thickness of the London clay at Alum Bay at the expense of the Bagshot beds, and diminishes that of the Bracklesham beds at Whitecliff Bay by transferring part of them to the Lower Bagshot.—Notes on certain modes of occurrence of gold in Australia, by Richard Daintree, F.G.S.—Notes on the geology of the Island of Mauritius and the adjacent islets, by W. H. T. Power, B.A. (Communicated by W. Whitaker, F.G.S.)

Entomological Society, February 6.—H. W. Bates, F.L.S., F.Z.S., president, in the chair.—Prof. J. O. Westwood, Mr. J. W. Douglas, and Mr. F. Smith, were nominated by the president as vice-presidents for the year.—Mr. Rich. S. Standon and Mr. T. W. Wonfor, were elected Members of the Society.—Mr. J. Jenner Weir exhibited the following spiders: three species identified by Sir Sydney Saunders as *Atypus sulzeri*, taken at Lewes; a remarkable form from Madagascar, and a small species beaten out of trees in the New Forest, which in marking and coloration, resembled lichen.—Mr. McLachlan exhibited a small collection of dragon-flies in illustration of a paper he communicated entitled "Calopterygina collected by Mr. Buckley in Ecuador." The collection contained a fine series of a new species, *Euthore mirabilis*.—Mr. Meldola exhibited a remarkable specimen of *Leucania conigera*. The colour and markings of the fore-wings were reproduced in the lower half of the left hind-wing.—Mr. Meldola read extracts from a letter addressed to Mr. Chas. Darwin from Dr. Fritz Müller, St. Catharina, Brazil, containing some valuable observations on the discrimination exhibited by a number of butterflies for certain colours in flowers. Mr. Müller also described the odoriferous organ of a male sphinx-moth which exhaled a strong musk-like odour, and called attention to a secondary sexual character observable in some species of Callidryas and other Pierinæ, in the serration of the costal margin of the anterior wing. This is confined to the males, though sometimes found in the females of Callidryas Philea, but in a far less degree.—Reference was made to a sphinx-moth, the proboscis of which, measuring 22 centimetres, had been forwarded by Mr. Müller and was exhibited at the meeting.—Mr. A. G. Butler stated that he had measured the probosces of all the Sphingidæ from Madagascar contained in the British Museum, and found that none of them exceeded 5 inches in length. He also stated that the Callidryades in the British Museum with serrated costal margins to the fore-wings, included the males of all the species of the genera Catopsilia, Phœbis, and Callydryas (true), with the addition of one or two other species. The President observed that in the genus Prioneris the serrated costal margin existed in both sexes.—The Secretary, on behalf of Capt. Elwes, exhibited some coloured illustrations of butterflies which had been taken by a new process of nature-printing.—Mr. G. C. Champion exhibited a specimen of the rare British beetle *Anthicus bimaculatus*, taken at New Brighton, and some specimens of the genus Cetonia, from the Mediterranean region.—Mr. J. W. May exhibited a specimen of *Carabus intricatus*, which he described as taken, for the first time, in the neighbourhood of London.—Mr. H. Goss called attention to the occurrence of sexual dimorphism in *Erebia medea*, exhibiting specimens of both forms of the female.—Sir John Lubbock read a paper on the colouring of British caterpillars. Accepting the principle laid down by Mr. Darwin and others, that dull-coloured, green, and smooth-skinned caterpillars are eaten by birds, &c., whilst spiny, hairy, and brightly-coloured species are rejected, the author stated that by the statistical method it was shown that no hairy caterpillars are green, whilst, on the other hand, a large majority of black and brightly-coloured species are hairy or otherwise protected.—Mr. Meldola read extracts from a recent communication by Dr. Fritz Müller in *Kosmos* on the subject.—The following papers were communicated by Mr. C. O. Waterhouse:—"Description of a new Dragon-fly (Gynacantha) from Borneo," "Description of a new Species of Chernetidæ (Pseudoscorpionidæ) from Spain," "On the Different Forms occurring in the Coleopterous Family *Lycidæ*, with Descriptions of New Genera and Species."

PARIS

Academy of Sciences, March 4.—M. Fizeau in the chair.—The following papers were read:—On the theory of the telephone, by M. Du Moncel. The theory of speech being transmitted by electro-magnetic action causing the plate of the receiving telephone to repeat the vibrations of the sending one, is, he thinks, untenable. The plate in the receiving instrument merely strengthens by reaction the magnetic vibrations of the bar, which seem to be due to contractions and dilatations of the magnetic molecules, through being successively magnetised and demagnetised. Induced currents probably owe their advantage for this work to their *instantaneity*. Their greater or less intensity is of small account.—The vibrations of matter and the waves of the ether in photo-chemical combinations, by M. Favé.—Report of Committee on the importance of preservation of certain erratic blocks situated on French territory, and on the work of MM. Falsan and Chantre, on ancient glaciers and the erratic region of the middle part of the Rhône valley, by M. Daubrée.—On the telluric etiology of cholera, by M. Decaisne. Cholera appears on all geological formations, but its development and propagation depend largely on the physical aggregation of the ground, its permeability for water and air, and the variable quantity of water it contains. The partisans of the telluric doctrine always suppose a specific infectious substance or cholera germ, which is propagated from place to place by human communications, not by the atmosphere.—Study of the resistance of the air in the torsion-balance, by MM. Cornu and Baille. Eliminating accidental perturbations, they have established these two laws: (1) The amplitudes or distances of two successive elongations decrease in geometrical progression; (2) The epochs of the elongations are in arithmetical progression. One theoretical consequence is that the resistance of the surrounding air to the movement of the lever is proportional to the first power of the angular velocity of the lever.—Influence of electricity on evaporation, by M. Mascart. Small basins containing water or moistened earth were placed under conductors (having the form of circular gratings), which were electrified by a Holtz machine driven by a water-motor, and were kept in a constant electric state. The evaporation was thus constantly increased, sometimes even doubled. Inequalities of temperature, however, veil the influence of electricity; the basins were inclosed in a large case, the air in which was regularly dried, and in winter the operation was performed in a kind of subsoil.—Observations on gallium, by MM. Lecoq de Boisbaudran and Jungfleisch. *Inter alia*, the authors exhibited anhydrous chloride, bromide, and iodide of the metal.—Discovery of a small planet at Clinton, New York, by Mr. Peters.—Theory of Vesta, by M. Perrotin.—On the employment of particular solutions of a differential equation of the first order and the first degree, in the investigation of the general integral, by M. Darboux.—On the fundamental points of the group of plane curves defined by a differential equation of the first algebraic order, by M. Fouret.—On the sumnatory formula of Maclaurin, by M. Callandreau.—On the elastic forces of vapours emitted by a mixture of two liquids, by M. Duclaux. A mode is indicated of calculating beforehand the boiling temperature of a liquid of known constitution.—Theory of the new direct-vision spectroscope, by M. Thollon.—On the combustion of gases, by M. Schutzenberger. This relates to the propagation of combustion in eudiometers. The chief conditions affecting the phenomenon are: pressure of the gas, length of the gaseous column, composition of the mixture, and diameter of the tube.—On two allotropic varieties of magnetic oxide of iron, by M. Moissan. Sesquioxide of iron heated in an atmosphere of hydrogen or carbonic oxide to 350° or 440°, is transformed in a few hours into magnetic oxide; but this is very different in properties from the magnetic oxide got at a high temperature, by decomposing water with iron at a red heat or burning iron in oxygen, or decomposing sesquioxide at a lively red.—On the action of fluoride of boron on anethol; study of fluorhydrate of fluoride of boron, by M. Landolph.—New carbonated cupric liquor for determination of glucose, by M. Pellet.—On lactic fermentation, by M. Boutroux. He describes the form of the organism present and its mode of action.—Researches on the chemical composition and the functions of the leaves of plants, by M. Corenwinder. The predominance of azotised substances in young leaves indicates that it is these substances which exercise the respiratory function (absorbing oxygen and exhaling carbonic acid). Phosphorus too is in much less quantity in the older leaves, which again are rich in calcareous salts, and the chlorophyll in them retains and decomposes the CO_2 emanating from respiration.—Researches on the maturation of olives, by M. Roussile.—On the mineral water of Challes, in Savoy, by M. Willm.—On the frequency of glaucoma on the north coast of Africa, by M. Gayal.

EASTERN EXCAVATIONS

Mycenæ. A Narrative of Researches and Discoveries at Mycenæ and Tiryns. By Dr. Henry Schliemann. (London: Murray, 1878.)

Troy and its Remains. A Narrative of Researches and Discoveries made on the Site of Ilium and the Trojan Plain. By Dr. Henry Schliemann. (London: Murray, 1875.)

Exhibition of Antiquities from Hissarlik at the South Kensington Museum. By Dr. Henry Schliemann.

Cyprus: its Ancient Cities, Tombs, and Temples. A Narrative of Researches and Excavations. By General Louis Palma di Cesnola. (London: Murray, 1877.)

TWO Eastern questions occupy the attention of Europe at the present time—one relating to the present, and, it is to be feared greatly, to the future; the other has reference to the past, and to the bridging over of that little-known protohistoric period which connects the civilisation of the far east, that is, Egypt and Assyria, with the culture of ancient Greece, to which we western Europeans are so much indebted. Different conditions of thought are engaged in the study of these two questions, yet both are connected, for the present crisis in the East represents the returning current of that same stream of culture which was flowing westward towards the dawn of our era. What Egypt and Assyria lent to Greece she passed on to Etruria and Rome, and the Romans carried to the shores of the Atlantic, there developing and fructifying, it has passed back eastward in a return wave, reviving the ancient monarchies in its path. Rome has regained its ancient landmarks. Germany has consolidated. Austria has been pushed, and is still pushing eastward. Greece is proclaiming the revival of its ancient nationality, and this will doubtless be followed in times to come by the resuscitation of Egypt and Palestine. The Turk, representing the last wave of the western flow, has been met and swamped by the returning ebb.

The time has been well chosen by our archæologists for an examination into the sites of those ancient cities whose history corresponds most closely to the period on which we are now entering; and to us English the parallel between the two eras has special interest. At a time when our fleets are massing in these seas in order to keep open our communication with the East, we are reminded that it was by means of a seafaring people that civilisation was spread over this region in ancient times. The comparison between ourselves and the Phœnicians has been often drawn; like causes produce like results. For the same reason that they peopled the shores and islands of the Mediterranean with their colonies, we have caused them to be studded with our military posts. What the Phœnicians did for the flow of civilisation in days of old, we, if we fulfil our functions rightly, shall do for its returning ebb at the present time. Other European nations are concerned in continental movements, but, like the Phœnicians, our path is by the sea. Syria, Cyprus, Crete, and Greece was the line they traversed, and this is the line which sooner or later we appear destined to occupy in the struggle to come.

It is not well to carry a simile too far, but one other parallel, as a natural outcome of the instincts of the two people, may be fairly drawn. It is said that in art, in modern times at least, we have no style of our own. Neither had they; devoted to navigation and commerce, their art, instead of being indigenous, was borrowed from the nations with whom they traded. This is well shown in the collection of antiquities from Cyprus, for the knowledge of which we are indebted to General di Cesnola, the American consul in that island. Cyprus was one of the first islands colonised by the Phœnicians. Three distinct styles of art are recognised in the Cypriote pottery, sculptures and glyptic representations, the Assyrian, the Egyptian, and the Greek. In the temple of Golgoi the objects belonging to these three different styles were found separately placed, the Egyptian by themselves, the Assyrian in like manner, and the Greek also together, showing in the opinion of the author that they were collected at different epochs, spreading over a long series of years. On the other hand a considerable number of the objects figured in General Cesnola's book distinctly include both the Assyrian and the Egyptian, for example, in the patera from Curium, figured in p. 329; the centre figure represents a winged warrior, probably a king, fighting with a lion, which is in true Assyrian style, whilst the outer circle of the same vessel is ornamented with figures that are as purely Egyptian. Probably between the eighth and tenth centuries B.C. both styles may have prevailed in Cyprus at different times, but it is evident that a period arose in which both styles as well as the Greek were united, and closely imitated, and this constitutes the chief characteristic of the Cypriote art.

Very different in this respect are some of the objects discovered by Dr. Schliemann in the royal tombs at Mycenæ, which, though rude and barbarous—more so, indeed, than the majority of the Cypriote antiquities—nevertheless show some attempt at realism. More especially may be noticed the bull's head, the bas reliefs, and some of the gold ornaments. In these we perceive an absence of that servile imitation of earlier styles which has been noticed as the characteristic of Cypriote art; and although falling far short of Hellenic greatness, there is a freedom from conventionality which left the artist at liberty to turn to nature as his instructor, and thus, with the aid of a little imagination, we may perhaps recognise potentially in these rude designs the germs of those qualities which made Greek art so famous in the times that followed.

The concentric circles of the Cypriote ornamentation are here replaced by a system of coil ornaments which resemble those in use during the bronze age of Europe rather than anything to be found in the countries immediately to the eastward. Notwithstanding this, however, the connection with Cyprus is apparent in many of the forms. The rude terra-cotta figures of men and animals correspond very closely with those found in Cyprus as well as Rhodes, and the long-nosed warriors drawn on the fragment of a painted vase (p. 133, "Mycenæ") might clearly claim family relationship with the lady figured on the Cypriote vase in Fig. 394 of General Cesnola's work. The mode of ornamenting the eyebrows by means of parallel incised lines is distinctly Cypriote. But perhaps the objects which most clearly attest the connection between the two places are the golden diadems (p. 186 "Mycenæ") found on the heads of the bodies in the tombs. These consist of pointed oval plates of gold, sometimes highly ornamented and having at the points, small holes by which they were fastened round the head with a wire. The position of the graves in which similar diadems to these were found at Idalium in Cyprus proves distinctly that they were more recent than the graves of the Phœnician period which lay beneath them. Similar forms of golden diadems from Kouyunjik are in the British Museum. The golden diadems found at Idalium are shown by these associated remains to belong to a more advanced period of art than the larger and more massive ones discovered in the royal tombs in the Agora at Mycenæ, the former being probably of the Greco-Roman age. Nevertheless the identity of the forms ought not to escape attention when considering the relative antiquity of the finds; they were, as Dr. Schliemann truly remarks (p. 189), in very extensive use in early times, and an investigation into the origin of these peculiar brow ornaments will without doubt have an important bearing on the period of the interments with which they are associated. It is to be regretted that General Cesnola, although he mentions the finding of these diadems in p. 75 of his work gives no illustration of them, but a number of them were sold at Sotheby's some years ago, and the remarks here made are based upon observations made at the time of the sale.

Turning now to Hissarlik our attention is naturally drawn in the first place to the so-called owl-faced vases which form so large a proportion of the antiquities discovered by Dr. Schliemann there. No subject has been more frequently applied to the ornamentation of funereal and other vases than the representation of a human face, as examples of which we may call to mind the rude jars representing Besa or Typhon in the Egyptian department of the British Museum, or our own Bellarmin jugs of the sixteenth century. Such representations are usually at first realistic, and expressive of the best endeavour of the designer, but in process of time the forms suffer degradation in the hands of inexpert or hasty workmen; the transmutation of form observable on British coins affords a well-known illustration of the gradual changes produced by means of imperfect copies, and similar degradation is often seen in the tribal and other ornaments and badges of modern savages. On the pottery found in the Peruvian graves a human face is of frequent occurrence. Some of these figures of faces are equal to the best productions of Cyprus or Mycenæ, whilst in others the features are so much dwarfed and distorted that little more than a line for the eyebrows and another for the nose remains to denote the intention of the potter, the other features having disappeared in those examples in which nothing more than a rude symbolism has been aimed at. An examination of the large collection of vases from Hissarlik, now exhibited by Dr. Schliemann at South Kensington is sufficient to show that this has been the true history of the γλαυκῶπις, or "owl-faced Goddess Minerva." In some of these vases all the features of the human face are present; in others some of them disappear or become conventionalised; the mouth is no longer represented, and the nose shrinks into a small beak-like projection beneath the eyebrows. Yet if the form of it is looked at carefully, it will be seen that it is still a nose, and in no case has it been the intention of the potter to represent a beak; its position is never that of an owl's beak beneath the line of the eyes. The eye of an owl is surrounded on all sides by a complete disc of feathers, but in no single instance has the lower and inner side of such a disc been represented on these vases; even in the most degraded examples the line which sweeps round the upper and outer portions of the eye is still seen to be an eyebrow, which is a feature that is entirely wanting in an owl. In many cases the ear has been retained, where the mouth has disappeared, and the ear is still distinctly human. It may be safely said that there is no example in the whole collection at South Kensington in which the form of an owl's face has been intentionally represented. In like manner the long upright projections on the sides of some of the vases, which, when associated with the symbolic features above spoken of, have been said to represent the wings of an owl, can be shown by a selected series to be nothing more than the handles of the pots developed and adapted to use in another form. Other handles, of which most of the pots are provided with three or four, have been dwarfed so as to dwindle into a mere reminiscence, marked by slightly raised lines on the sides of the vessels. Similar developments of handles may be seen in the specimens of terra-cotta lamps exhibited by the Palestine exploration committee at South Kensington. Then again, the small flat stone objects figured in page 36 of Dr. Schliemann's book, "Troy and its Remains," and supposed by him to be Athena idols, are clearly nothing more than symbolic vases. The lines denoting the face on these stone objects represent the face on the vases, the head, neck, and body of the vase and the horizontal lines across the neck marking the separation between the cover and body of the vase are all shown on these miniature models, which correspond to the stone models of vases which at a later period replaced those previously employed in Egyptian tombs, and it was no doubt by means of some such symbolism that these model vases at Hissarlik came to be introduced.

The peculiar "crown-shaped" covers found by Dr. Schliemann at Hissarlik, and figured at page 25, are of interest, and serve by their form to fix the position of the Hissarlik antiquities in point of sequence. These crown-like lids are survivals of the neck and handles of earlier forms whose history is to be traced in other parts of the Levant. The form of vase with two handles, one on either side joining the mouth and body of the vessel, of which a good example is represented on page 102 of General Cesnola's work, appears to have given rise to a shape with a closed or dummy neck, in which the form of the neck and handles are retained, but the real opening is in a funnel-shaped mouth adjoining the dummy neck. Dr. Schliemann found specimens of these altered vases in the tumulus at Sparta and also at Mycenæ. An illustration of one from the latter place is given at page 64 of his work on Mycenæ. They are common in Rhodes, examples of which may be seen in specimens from Ialysos, in the British Museum. They are also found in Attica, Cyprus, and in Egyptian tombs. The "crown-shaped" covers found at [illegible]sarlik represent a further degradation of this form in which the neck has disappeared, the mouth and handles only remaining. Three and four handles have been substituted, in some cases, for the double handle of the earlier vessels. The cover, with the dummy mouth and handles, of course occupies the position previously occupied by the true neck and handles on the top of the vase. As these crown-shaped covers are found in the lowest stratum, the "earliest city" discovered by Dr. Schliemann at Hissarlik, it follows, if the history of these forms has been correctly stated above, that the whole of the Hissarlik antiquities are of comparatively recent protohistoric date, though belonging, no doubt, to a people in a barbarous condition of culture, which accounts for the number of rude stone implements found from top to bottom throughout the excavations.

The so-called crest of the helmet of Athena (p. 283, Hissarlik), is a further degradation of these crown-shaped tops, and represents the dwarfed survival of one of the handles, the connecting links being represented by three specimens in the collection at South Kensington, where the vestiges of all three handles are shown in their proper places, and these were subsequently replaced by one, transferred for convenience' sake from the position formerly occupied by the three to the centre of the lid. In short, the history of every form may be traced by connecting links in the specimens exhibited at South Kensington, the whole collection forms a continuous sequence which, by judicious arrangement of connected forms, is capable of demonstration, and it is to be hoped that some such arrangement may be adopted before this interesting collection leaves the place. To apply the expression "Darwinism" to such a sequence of forms is no mere figure of speech, it expresses the truth as fully in its relation to savage art and ornament as to the forms of nature. Conservatism, acquired habits, and incapacity for improvement on the one hand, love of variety, economy of time and trouble, and imperfect copying on the other, combine to produce those slow and gradual changes which are characteristic of all barbarous art. Every object marks its own place in sequence by means of its form, and it is the recognition of this principle which supplies the place of written records in those prehistoric and protohistoric phases of culture with which we are dealing. Earlier forms are retained side by side with the more advanced ones and are applied to those objects and uses for which they appear fittest. If any evidence were wanting to disprove the absurd imputations that have been cast upon the genuineness of these antiquities, these connected varieties would alone suffice to prove that they were the work of a people in a very primitive condition of civilisation. Whatever difference of opinion may exist as to some of Dr. Schliemann's deductions no reasonable archæologist will be found to dispute the extraordinary merit of his discoveries. We are glad to hear that he is about to resume his excavations at Hissarlik. To the deep research and disinterested enthusiasm which has already placed him in the front rank of explorers, will now be added a large amount of archæological experience and knowledge of allied forms that he has acquired since his first excavations were conducted at this place, leading us to hope that his future discoveries will exceed them all in interest and importance.

PROFESSOR BELL'S "SELBORNE"

The Natural History and Antiquities of Selborne, in the County of Southampton. By the late Rev. Gilbert White, formerly Fellow of Oriel College, Oxford. Edited by Thomas Bell, F.R.S., F.L.S., F.G.S., &c., Professor of Zoology in King's College, London. 8vo. 2 vols. (London: Van Voorst, 1877.)

THE edition of this classic work for so many years expected from the hands of Prof. Bell, has at length appeared, and readers will regard it with much gratification and a little disappointment. The former feeling will arise from the large amount of new matter which it contains, and the latter from the conviction which cannot but force itself upon them that more was to be made of the whole than the editor seems to have been aware of. Yet Prof. Bell's long life—it is more than fifty years since he first won his spurs in the field of science—and his invaluable services in so many departments of zoology, render us very unwilling to say more than we are compelled in detraction of this, his latest labour, and the child of his old age. He writes now, as he always has written, pleasantly enough, but he fails to give us the notion that he has done the best he could with the materials placed at his disposal, and with his other unequalled opportunities. It is evident that his task grew upon him, and that a considerable portion must have been printed off before its extent was determined. This, indeed, is not an uncommon thing with young authors and editors; but Prof. Bell's literary experience, and the long time he is known to have had the present work in preparation, should have guarded him from an error of the kind. We might almost infer that when the memoir was written he had not mastered all the details of the deeply interesting correspondence which forms the bulk of his second volume, and certainly that he had not decided how many, and which, of the letters it contains should be given to the world. It is sufficient for us now to say that there is not one of them that could have been spared, for we must presently return to their consideration.

That any memoir of Gilbert White must, from the scarcity of facts relating to him, give a meagre account of that great and estimable naturalist, we are ready to admit, and that Prof. Bell's is at the same time far more copious than any other that has been published, will be obvious to all who are acquainted with the subject. But we cannot help regretting that the chief biographical facts have not been set forth in a clearer light than they appear, and proper as it is to tell us something of all the members of the family, we unfortunately find least is told us of those members of whom we should like to know most. Gilbert White had three brothers who were distinctly men of capacity above the average, beside two others much less, or hardly at all, distinguished. Of the former, Thomas, we are told, was successful in trade, and became a F.R.S., but in what trade or when he died we are left ignorant. Benjamin was the well-known publisher of natural history books—among others of Pennant's—for whom Prof. Bell has some hard words, not, perhaps, wholly undeserved, but it is very probable, to say the least, that had not Gilbert, through his brother, become acquainted with Pennant the "Natural History of Selborne" would never have been written. The third remarkable brother was John, who was for a considerable time chaplain at Gibraltar, of which place he wrote a zoology that unfortunately was never printed, and of which the manuscript seems to have vanished, though Prof. Bell says the introduction to it is in his possession. Pity it is he has not given us this fragment, for some of the hints and suggestions that Gilbert was always imparting to John, his "most steady and communicative correspondent," must surely be therein contained, and it could not fail to have been a valuable addition to these volumes. In the next generation were "Jack," son of the aforesaid John, and a pupil of Gilbert's, who thought highly of him, and Samuel Barker, another nephew, an agreeable and evidently valued correspondent of his uncle's. It seems hardly possible but that diligent research would not have recovered more of these younger men than we find here recorded.

Of Gilbert himself we doubt not Prof. Bell has done all in his power to gather information, and in some respects he has been successful. Born at Selborne in 1720, he went to school at Basingstoke, and to Oxford in 1739. There he graduated B.A. in 1743, and the following year was elected to a Fellowship at Oriel, which he enjoyed till his death. Taking orders he successively held two curacies in Hampshire, one at Selborne till 1752, when he filled the office of Proctor (*Junior* Proctor, Prof. Bell is careful to tell us) for a year. Then he took another Hampshire curacy for a couple of years, at the end of which time he came once more to live at Selborne, which remained his home till his death. In 1757 he accepted the living of Moreton-Pinkney, in Northamptonshire, but the preferment must have been small, as it did not incapacitate him from holding his Fellowship, and, according to the custom of the times, residence was not required of him. The following year his father died, but he did not come into the family property at Selborne—"The Wakes," now possessed by Prof. Bell—until the death of an uncle in 1763. He seems to have made Pennant's acquaintance about 1767, or perhaps a little earlier. In 1768 we find him writing to Banks, and the following year began his correspondence with Barrington, who, in 1774 and 1775, communicated to the Royal Society those ever-memorable monographs of the British *Hirundines*, which first made known White's powers of observation and felicity of expression. In 1774 he refused no fewer than three college livings, for he was doubtless in easy circumstances, and once more accepted the curacy of his birth-place. At the age of sixty-nine his single book was published, and he survived its appearance just four years. Another event in his life must be noted here—his attachment to the sister of his college friend Tom Mulso. What hindered their union does not appear, but in 1760 the lady was married to Mr. Chapone, and was subsequently the authoress of several well-known works, and a celebrated "blue-stocking." We have to thank Prof. Bell for collecting most of these facts and dates now for the first time published, but they are not very easily gathered from his memoir.

Of course we have no occasion here to review the letters to Pennant and Barrington which formed the original "Natural History of Selborne." Their place in literature and science is assured. It were impertinent to speak of their merits, or to indicate their few—very few—defects. Being the results of the personal experience of their author they will hold their ground for all time. Never before, perhaps, was there so careful an observer, and since, we know of but one other so accurate. That other has no doubt surpassed his predecessor in the ingenuity of his induction and the versatility of its application, but it is no detriment to Gilbert White that he should be ranked as an observer second only to Mr. Darwin. Numerous editors have tried their hand in annotating this ever-popular work, and many more will make the same attempt. Prof. Bell is chary—too chary, perhaps, of his comments—but if he errs he errs on the safe side, and readers who have been disgusted with the inanity or the flippancy of the notes to some recent editions, will rejoice that in him they have an editor whose remarks, if they be but few, are always to the point, and never in bad taste.

Now we ought to consider the new letters, but the length of this article warns us that we must be brief in what we say of them. They remove the present edition from comparison with any other, and we have sincerely to thank Prof. Bell for having shown us, by printing them, that White was even more than had formerly appeared. Every grace of style, every power of thought—in a word, every good quality which was foreshadowed in the famous epistles to Pennant and Barrington is doubled, or more than doubled in intensity in the letters now given to the public—letters, too, which were never prepared by their writer for publication. We have him before us as the instigator to good works, the sage adviser in matters literary and scientific, the self-denier, the man of affectionate relations, the man of high aspirations, yet humble; simple, yet full of humour; a recluse, yet a man of the world in the best sense. We long to subjoin extracts from them, but want of space renders that impossible. Our readers will read and judge for themselves. It must suffice to say that there are more than one hundred from Gilbert's pen, of which scarcely a dozen have ever been printed before, in addition to a most interesting correspondence between John White and Linnæus on the zoology of Gibraltar, and letters from various members of the family which faithfully reflect, as it were, in a remarkable manner Gilbert's own nature, besides a few—too few, unfortunately—addressed to him by men like Lightfoot, Skinner, Montagu, and Marsham. For the sake of these we readily forgive all the shortcomings of the present volume—even the want of a table of contents and of a good index.

OUR BOOK SHELF

Proceedings of the London Mathematical Society, vol. viii. (November, 1876, to November, 1877), 321 pp. (Messrs. Hodgson.)

THIS goodly-sized volume bears testimony to the activity of its members, and contains twenty-nine papers, published *in extenso*. We may specially refer to one or two. The "Pure" side of the subject of mathematics, as usual, is the favoured one, and furnishes memoirs by Prof. Cayley on the condition for the existence of a surface cutting at right angles a given set of lines, on a general differential equation, geometrical illustration of a theorem relating to an irrational function of an imaginary variable, on the circular relation of Möbius and on the linear transformation of the integral $\int \frac{du}{\sqrt{U}}$.—Prof. Clifford has an excellent paper on the canonical form and dissection of a Riemann's surface. Prof. H. J. S. Smith contributes the conditions of perpendicularity in a parallelepipedal system, and a very interesting presidential address on the present state and prospects of some branches of pure mathematics. Mr. Spottiswoode writes on curves having four-point contact with a triply infinite pencil of curves, and Prof. Wolstenholme gives an easy method of finding the invariant equation expressing any poristic relation between two conics.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Trajectories of Shot

I HOPE you will be able to afford me space for a few remarks on the following extract from a paper on the Trajectories of Shot, by Mr. W. D. Niven, which appeared in the *Proceedings* of the Royal Society for 1877.

Mr. Niven arranges his paper under three heads, calling them the first, second, and third methods. The third method is the one he favours, while he endeavours to dispose of the other two in the following terms:—

"§ 11. It will be observed that the two foregoing methods each open with the same equation (a). Now there is a serious difficulty in the use of that equation. Suppose, for example, we were to integrate over an arc of 1°, we should have to use the mean value of k between its values corresponding to the velocities at the beginning and end of the arc. But we do not know the latter of these velocities; it is the very thing we have to find. The first steps in our work must be to *guess* at it. The practised calculator can, from his experience, make a very good estimate. Having made his estimate, he determines k. He uses this value of k in equation (a), and if he gets the velocity he *guessed* at, he concludes that he *guessed* rightly, and that he has got the velocity at the end of the arc. If the equation (a) does not agree with him, he makes *another guess*, and *so on till he comes right*."

The case would be indeed hopeless, if all this was quite correct. But I have to inform Mr. Niven that, in all proper cases v_β may be found *accurately* from equation (a), and without any "guessing" whatever. Taking Mr. Niven's own solitary example, I will *calculate* the value of v_β at the end of an arc, not of 1°, but of 3°, and compare my result with his own. The initial velocity, v_α, is here 1,400 f.s., and the corresponding value of the coefficient k_α, given in my table, is 104·0. Substitute this value for k in equation (a), given below, and v_β will be found 1291·7 f.s., a *first* approximation. Now *calculate* the mean value of k between velocities 1,400 and 1,290 f.s. by the help of the table, and it will be found to be equal to 106·3. Substitute this new value of k in equation (a), and v_β will be found 1289·8 f.s., a *second* approximation. We must stop here, because if we attempted to carry the approximation further, we should obtain the same value of k, and therefore of v_β, as in the second approximation. Mr. Niven finds $v_\beta = 1290$ f.s.

Of course in ordinary cases, a calculator, in making his first approximation to v_β, would commence by taking a value of k corresponding to a velocity *somewhat below* the initial velocity. In this way a better *first* approximate value of v_β would be found. Thus, again referring to Mr. Niven's own example, I will take a step over an arc of 6°, from $\alpha = +3°$ to $\beta = -3°$. The initial velocity is 1,400 f.s. I now go so far as to "guess" that the mean value of k will correspond to a velocity considerably below 1,400 f.s., and take $k = 107·9$, corresponding to a velocity 1,300 f.s. This gives $v_\beta = 1208·1$, a *first* approximation. The mean value of k between 1,400 and 1,210 f.s. is now found to be 107·2, which gives $v_\beta = 1209·0$ f.s. Mr. Niven obtains 1207·4 by stepping over two arcs of 3°. If any further adjustment was required, proportional parts might be used, seeing that a correction $\delta k = -0·7$ gives $\delta v_\beta = +1·8$.

Mr. Niven then proceeds to question the *accuracy* of what he is pleased to call the "process of guessing," as follows:—

"It seems to me, however, that this method of going to work, leaving out of account the loss of time, is open to objection in *the point of accuracy*. For, first there is no method of determining on what principle the mean value of k is found—what manner of mean it is. Again, let us suppose for an instant that the velocity at the end of the arc *guessed* at, and the value of k, are in agreement; that is to say, let the equation

$$\left(\frac{1,000}{v_\beta}\right)^3 \sec^3\beta - \left(\frac{1,000}{v_\alpha}\right)^3 \sec^3\alpha = \frac{d^2}{w}\frac{k}{g}(P_\alpha - P_\beta) \text{ — (a)}$$

hold for the values of v_β and k used by the calculator. It by no means follows that he has hit on the right value of v_β and k. For if he is dealing with a part of the tables in which $\frac{dk}{dv}$ happens to be nearly equal to $-3\frac{wg}{d^2}\frac{\sec^3\beta}{P_\alpha - P_\beta}\frac{(1,000)^3}{v^4}$, it is obvious that there are ever so many pairs of values of v_β and k which will stand the test of satisfying the above equation. Now an examination of Mr. Bashforth's tables for ogival-headed shot shows that the value of k diminishes as v increases from 1,200 feet upwards, so that $\frac{dk}{dv}$ is negative for a considerable range of values of v which are common in practice. It is not at all unlikely, therefore, that the value for $\frac{dk}{dv}$ just stated may often be very nearly true; in which the case the *process of guessing* becomes extremely dangerous."

I here observe that Mr. Niven is not entitled to assume that, because two quantities have the *same sign*, they will therefore be probably often nearly of *equal value*. Without discussing the value of his test of danger, I have to state that my tabular value of $\frac{\delta k_\beta}{\delta v_\beta}$, for velocities above 1,200 f.s., lies between 0 and −0·09. I have calculated the numerical values of Mr. Niven's expression for $\frac{dk}{dv}$, for shot fired from various guns, from the Martini-Henry rifle up to the 80-ton gun, and have always obtained a numerical result so far outside the limits of the tabular value, that, for the present, I conclude that Mr. Niven's condition (whatever may be its value) *is never nearly satisfied in any practical example.* But when a practical case is produced where "ever so many pairs of values of v_β and k," *differing sensibly*, "stand the test of satisfying the above equation" (a), it shall receive my best attention.

It is well known that the problem of calculating the trajectory of a shot, like so many other practical problems, does not admit of a direct and complete solution. So that all solutions, being approximations, are more or less erroneous. But I feel perfect confidence in the results given by my methods of calculation, because, the smaller the arcs taken at each step, and the nearer the *calculated* will approach to the *actual* trajectory. But methods of approximation require to be used with judgment. For instance with the heaviest shot in use, we may take steps of 5° for velocities above 1,100 f.s.; while for small arm bullets arcs of half a degree will be quite large enough. In any case of real difficulty the remedy will be to divide the trajectory into smaller arcs.

From what I have said it appears that my method of finding the trajectories of shot, *when properly applied*, is neither a "process of guessing" nor yet "dangerous."

Minting Vicarage, March 8 F. BASHFORTH

Australian Monotremata

I AM surprised to find that "P. L. S." (vol. xvi. p. 439), was not aware that the Echidna *Tachyglossus hystrix*, is found in N. Queensland. For the benefit of your readers I may mention that the Australian Museum possesses a fine specimen of *T. hystrix* from Cape York. Mr. Armit, of Georgetown, Mr. Robt. Johnstone, and others, have frequently found them in various parts of Queensland. One specimen from Cape York was obtained there by our taxidermist, J. A. Thorpe, in 1867.

The Platypus (*Ornithorhynchus anatinus*) is also found in Queensland as far north as the Burdekin at least, perhaps further.

Tachyglossus, strictly speaking, has no pouch, but the *areola* is sunk in the skin, and when the young are first born this depression, or miniature pouch, is large enough to hold them; when about a month or so old, their hinder parts may be seen sticking out; when two or three months old, only the head, and afterwards, as they become larger, only the snout is hidden. the marsupial bones, which are well developed, support the weight of the young one while sucking. The young does not leave the mother until at least one-third grown, and *even when fully the size* of the adult, the quills are only then beginning to show through the skin, which is black, and thinly covered with black hair.

The new species, *T. lawesii*, Ramsay, from Port Moresby, may be distinguished at once by the stiff flat bristles of the face and the more cylindrical form of its spines; *T. bruijnii* has a very long snout, nearly twice the length of any other species at present known. See *Proceedings* L. Soc. of N. S. W., Vol. ii., Pt. I. Pl. I.

E. P. RAMSAY

Australian Museum, Sydney, January 25

P.S.—It may interest your readers to know that Messrs. Ramsay Bros., of Maryborough, Queensland, have a fine series of *eleven Ceratodus alive* in a large tank constructed for them. These fish have now lived and thriven well in confinement for over eighteen months. I was the first to send the Ceratodus in spirits to England, although I never got the credit of it; nor did any of those naturalists to whom I forwarded specimens through a friend at the Zoological Society, ever think it worth their while to acknowledge them. Had it been otherwise, living specimens would have found their way to England long since. It is a great mistake to suppose the Ceratodus is now common; they can only be obtained at certain seasons and in certain parts of the Rivers Mary and Burnet. The Osteoglossum (*Barramundi*), with which the Ceratodus (*Teebine*) is often confounded, is plentiful enough in the western waters of Queensland.

Fetichism in Animals.—Discrimination of Insects

I HAVE frequently noticed the fetichism of dogs, and was therefore much interested by Mr. G. J. Romanes' letter of December 27, which I have but just seen. Our terrier—a very queer character and a great warrior—is abjectly superstitious. He will not come near a toy cow that lows and turns its head, but watches it at a distance with nose outstretched. A vibrating finger-glass terrifies him; indeed he has so many superstitions that we often make him very miserable by working on his fears. I feel sure he constantly tries to understand, but never gets further than the sense of "uncanny"-ness. Dogs vary greatly as to this.

A propos of the discriminating power of insects. I have seen humming-bird moths deceived by sight. They were seeking in an open loggia, ceiled with wood, some dark place in which to hide; the pine wood was studded with brown knots. Again and again the two moths flew from knot to knot, felt and rejected them. At last they reached the open work—holes which looked much like the knots—and in them they hid themselves.

I was much struck at the time, as it appeared to me to show they possessed some dim sense of colour, but no defining perception of surface.

Cahirmoyle, Ardagh, Co. Limerick

Nitrification

IT seems right to direct attention to the fact that Bacteria were observed by Meusel to convert nitrates into nitrites; an abstract of which observations is to be found in the *Annals and Magazine of Natural History* for February, 1876; this abstract is copied from *Silliman's Journal* for January, 1876, where the reference to Meusel's paper will be found. This reference is *Ber. Berl. chem. Gesel.*, October, 1875.

No indication of their knowledge of these observations is to be found in Schloesing and Munk's paper in the *Comptes Rendus* (February, 1877) or in Mr. Warington's communication to NATURE, vol. xvii. p. 367.

The Wasp and the Spider

MAY I suggest a possible explanation of the curious case of spider-hunting by a wasp cited by Mr. Cecil; had the prey so accurately tracked by the wasp been anything but a spider, it would, indeed, have seemed an almost conclusive instance of hunting by scent; but when one recollects the fine line usually left by spiders as they go, it is evident that sight or feeling may have been the sense exercised, and that the fatal clue may have been the guide to the wasp.

ENTOMOLOGY AT THE ROYAL AQUARIUM

AN aquarium is put to its legitimate use when it is made the home of natural history exhibitions, and any attempt to rescue one from the too dominant sway of the showman deserves every support at the hands of science. The Entomological Exhibition, the opening of which at the Royal Aquarium we noticed last week, is also quite a novelty, though it is the outcome in a particular branch of the idea that led to the Loan Exhibition of Scientific Apparatus at South Kensington; as in that case the exhibitors are induced by no hope of prizes, but merely from the love of their science to lend their treasures. One learns from such an exhibition as this how much genuine love for natural history exists amongst men whose daily lives are devoted to manual labour, and that there are those who live within sound of Bow Bells, who make as good a use of their more limited opportunities as Edward in Banffshire. Here is a Mr. Machin, compositor by trade, whose long day's work has not prevented him from collecting and rearing a magnificent series of crepuscular and nocturnal moths, shown in twenty beautifully-arranged cases and accurately named; and the collections of some others are scarcely less noticeable in this respect. But apart from the interest attaching to some of the exhibitors, the material brought together affords an opportunity both to the entomologist proper and to the general naturalist not often to be met with. The greater portion of the whole exhibition is perhaps inevitably taken up with British lepidoptera, but these are not, as might be feared, an endless multitude of specimens of no special interest beyond their rarity and beauty, but are made to teach as well as please. Lord Walsingham, for example, shows the larvæ, pupæ, and imagines of nearly 370 species with the plants on which they occur—so that we have their complete life-history so far as it can possibly be represented to us. This, perhaps, from its scientific character and the beautiful means of preservation adopted, is the most interesting to the general naturalist, but there are others more limited, but scarcely less instructive—as those shown by the Messrs. Adams, in which the usual parasites are included in the series with each insect. Other instructive collections are those which illustrate the varieties of a single species; such is the set of specimens of *Colias edusa*, exhibited by Mr. Harper, a grand series showing insensible passages between perfectly distinct colourings. The influence of climate on colour is well illustrated in the melanic northern varieties of several species of moths, which are usually of a lighter colour in the south of England, the two varieties being placed side by side in the Yorkshire collections, and the results of selective breeding in the same direction in the photographs, unfortunately not specimens, of the common gooseberry moth, varying from nearly white to almost entirely dark. The moths and butterflies of the fen districts, which are now becoming so scarce, are represented by a very large collection by Mr. Farn. But one of the most interesting objects is a large white close-set web, in appearance like a cloth—some eight feet by four feet, spun by the larvæ of a moth, *Ephestia elutella*, that feeds on chicory. It is a portion only of a larger web, six times the size, formed on the walls and ceiling of a chicory warehouse in York, by the incessant marching to and fro of the well-fed larvæ. The threads composing it are less than $\frac{1}{1000}$ inch in diameter, and as they are nearly contiguous and eight or ten deep, the portion exhibited represents about 4,000 miles of their wanderings. When twisted into a rope, it has been made to support a weight of 56lbs. The foreign Lepidoptera also figure largely, and are naturally attractive from their beauty, and in General Ramsay's cases from Nepaul, for their rarity. This portion of the series, however, is chiefly valuable for the illustrations of protective mimicry which it affords. Admirable specimens of the leaf butterfly, *Kallima inachis*, with the varying tints of their under surfaces, are in Gen. Ramsay's collection, and Mr. Swanzy has a grand series specially arranged of Diademas and Papiliones mimicking—some in the females and some in both sexes—the nauseous smelling members of the Danaidæ and Acraidæ. Similar series are shown by Rev. J. A. Walker and Mr. Weir. The extraordinary differences between male and female in some butterflies is well illustrated by Mr. Briggs' collection of Lycænas.

The remaining orders are in some instances admirably illustrated, but by far fewer exhibitors. Dr. Powers' nearly complete collections of British coleoptera and British hemiptera, are among the best ever made; and Mr. Frederick Smith's hymenoptera, which supplied much of the material for the British Museum Catalogue, and Mr. Stevens' exhaustive collection of weevils, both the results of forty years' work, are here exhibited. A most instructive series of Grecian hymenoptera, with their galleries bored in briars, and some magnificent coleoptera from Ashantee, containing beautiful examples of *Goliathus Drurii*, complete the list of the more noteworthy objects. Some important orders are thus without special illustration here, but no doubt this will not be the last as well as the first of such exhibitions; and when it comes round to the insects again we may hope to see as complete sets of diptera or neuroptera as of other orders. It would be a great advantage to students if such exhibitions of limited classes could be periodically instituted by loan, and Mr. Carrington certainly deserves our thanks for the idea and its successful realisation.

THE GOVERNMENT RESEARCH FUND

THE following list of grants to be paid from the Government Fund of 4,000*l.* on the recommendation of the Royal Society, during the present year, in aid of scientific research, has been sent us for publication:—

Not Personal.

David Gill, 93, Wimpole Street, W.—To defray Expenses connected with a Determination of the Solar Parallax by Observation of the Diurnal Parallax of Mars ... £250

Rev. Dr. Haughton, Trinity College Dublin.—For Aid in the Numerical Reductions of the Tidal Observations made on board the *Discovery* and *Alert* in the late Arctic Expedition ... £75

Prof. Fleeming Jenkin, 3, Great Stuart Street, Edinburgh.—For Experimental Investigations on Friction ... £50

W. Chandler Roberts, Royal Mint, Tower Hill, E.—For Researches on Metals and Alloys in a Molten State passing through Capillary Tubes ... £25

J. Kerr, Free Church Training College, Glasgow.—For Continuation of Electro-Optic and Magneto-Optic Researches ... £50

J. Norman Lockyer, 16, Penywern Road, South Kensington, S.W.—For Continuation of Spectroscopic Researches £200

Dr. O. J. Lodge, University College, Gower Street, W.C.—For Investigations into the Effect of Light on the residual Charge of Dielectrics; on the Conductivity of Hot Glass, and other Transparent Conductors, on Electrolytic Conduction, and other Subjects ... £100

Thomas Stevenson, Hon. Sec. Scottish Meteorological Society, General Post Office Buildings, Edinburgh.—For Aid in carrying on a Simultaneous Series of Anemometrical Observations at different heights, and in sheltered and unsheltered situations ... £50

W. Galloway, Cardiff.—For further Investigation of the Explosive Properties of Mixtures of Fire Damp and Coal Dust with Air ... £100

Sir William Thomson, University College, Glasgow.—For Tidal Investigations ... £100

For Experiments in Magnetisation of different Qualities of Iron, Nickel, and Cobalt under varying Stresses and Temperatures ... £100

J. E. H. Gordon, Pixholme, Dorking.—For Continuation of Experimental Measurements of the Specific Inductive Capacity of Dielectrics ... £100

H. Tomlinson, 36, Burghley Road, Highgate Road.—For Researches on the Alteration of Thermal and Electrical Conductivity produced by Magnetism, and on the Alteration of Electrical Resistance produced in Wires by Stretching £100

Prof. H. Alleyne Nicholson, University of St. Andrew's; R. Etheridge, jun., Geological Survey Office, Edinburgh.—For Aid in examining the Fauna of the Silurian Deposits of the Girvan District, Ayrshire, and in publishing a Descriptive List of the same ... £75

R. McLachlan, 39, Limes Grove, Lewisham.—For Aid towards the Expense of Publication of a Revision and Synopsis of European Trichoptera ... £50

C. Callaway, Wellington, Shropshire.—For Aid in working out the so-called Eruptive Rocks of Shropshire, and in verifying certain points in Local Geology ... £25

H. T. Stainton, Mountsfield, Lewisham.—In Aid of the Publication Fund of the Zoological Record Association ... £150

Dr. J. W. Dawson, McGill College, Montreal.—For Aid in excavating Erect Trees in the Coal Formation of Nova Scotia, in Beds where they are known to contain Reptilian and other Remains ... £50

Dr. R. H. Traquair, Museum of Science and Art, Edinburgh.—For Aid in preparing and publishing a Monograph on the Carboniferous Ganoid Fishes of Great Britain ... £75

W. Saville Kent, St. Helier's, Jersey.—To pay for Microscopical Apparatus for the Further Prosecution of Investigations into the Structure and Life-History of certain Lower Protozoa £50

Dr. W. A. Brailey, 38, King's Road, Brownswood Park, Green Lanes, N.—For Researches on the Causes determining the Tension of the Globe of the Eye in Man and Animals, and on the Physiological Influence on this Tension of such Substances as Atropia, Daturin, Eserine, and Pilocarpine ... £25

E. A. Schafer, University College, Gower Street.—For Payment of an Assistant in Continuing his Histological and Embryological Investigations ... £50

H. Woodward, 117, Beaufort Street, Chelsea.—For Continuation of Work on the Fossil Crustacea, especially with reference to the Trilobita and other Extinct Forms, and their Publication in the Volumes of the Palæontographical Society ... £75

Prof. H. G. Seeley, 61, Adelaide Road, N.W.—For an Examination of the Structure, Affinities, and Classification of the Extinct Reptilia and Allied Animals ... £75

Dr. C. R. A. Wright, St. Mary's Hospital, Paddington.—For Continuation of Researches on Certain Points in Chemical Dynamics; on the Determination of Chemical Affinity in Terms of Electrical Magnitudes; and on some of the lesser-known Alkaloids ... £100

Prof. C. Schorlemmer, Owens College, Manchester.—For Continuation of Researches into (1) The Normal Paraffins. (2) Suberone. (3) Aurin ... £100

THE SOURCES OF LIGHT[1]

WHEN the sun rises in the morning, the darkness of the night seems to fade away, and, wherever we look, without or within, all the air and space about us appears to be full of light. When evening comes again, the daylight disappears, and the moon and the stars give us another light. In the house we start the lamps, and they give us another light. Out-of-doors, in the dusky meadows, we see the fire-flies darting about, and giving out pale sparkles of yellow light as they fly. We look to the north in the night and see the aurora, or we watch the lightnings flash from cloud to cloud, and again we see more light.

This light from sun and moon, the stars, the fire, the clouds, the sky, is well worth studying. It will give us a number of the most beautiful and interesting experiments, and by the aid of a lamp, or the light of the sun, we can learn much that is both strange and curious, and perhaps exhibit to our friends a number of charming pictures, groups of colours, magical reflections, spectres, and shadows. All light comes from bodies on the earth or in the air, or from bodies outside of the atmosphere; and these bodies we call the sources of light. Light from sources outside of the atmosphere we call celestial light, and the sources of this light are stars, comets, and nebulæ. The nebulæ appear like flakes and clouds of light in the sky, and the comets appear only at rare intervals, as wandering stars that shine for a little while in the sky and then disappear. The stars are scattered widely apart through the vast spaces of the universe, and they give out their light both day and night. The brightest of these stars is the sun. When it shines upon us, the other stars appear to be lost in the brighter light of this greater star, and we cannot see them. At night, when the sun is hid, these other stars appear. We look up into the sky and see thousands of them, fixed points of light, each a sun, but so far away that they seem mere spots and points of light. Besides these stars are others, called the planets, that move round the sun. These give no light of their own, and we can only see them by the reflected light of the great star in the centre of our solar system. Among these stars are the Moon, Venus, Mars, Jupiter, and many others. We might call celestial light starlight; but the light from the great star, the sun, is so much brighter than the light of the others, that we call the light it gives us sunlight, and the light from the other suns we call starlight. For convenience, we also call the reflected light from the planets starlight, and the light from our nearest planet we call moonlight.

Terrestrial light includes all the light given out by things on the earth, or in the air that surrounds the earth. The most common light we call firelight, or the light that that comes from combustion. When we light a lamp or candle, we start a curious chemical action that gives out light and heat. The result of this action is fire, and the light that comes from the flame is firelight. When a thunder-storm rises, we see the lightning leap from the clouds, and give out flashes of intensely bright light. Sometimes, at night, the northern sky is full of red or yellow light, darting up in dancing streamers, or resting in pale clouds in the dark sky. You have seen the tiny sparkles of light that spring from the cat's back when you stroke her fur in the dark, or have seen the sparks that leap from an electrical-machine. All these—the aurora, the lightning, and the electric sparks—are the same, and we call such light electric light.

Sometimes, in the night, we see shooting-stars flash across the sky. These are not stars, but masses of matter that, flying through space about the earth, strike our atmosphere and suddenly blaze with light. The friction with the air as they dart through it is so great that these masses glow with white heat, and give out brilliant light. Two smooth white flint pebbles, or two lumps of white sugar, if rubbed quickly together, will give out light, and this light we call the light from mechanical action.

Sailors upon the ocean sometimes see, at night, pale-yellow gleams of light in the water. A fire-fly or glow-worm imprisoned under a glass will show, in the dark, bright spots of light on his body. A piece of salted fish or chip of decayed wood will sometimes give a pale, cold light in the night; and certain chemicals, like Bologna phosphorus and compounds of sulphur, lime, strontium, and barium, if placed in the sunlight in glass vessels and then taken into the dark, will give out dull-coloured lights. All these—the drops of fire in the sea, the glow-worm, the bit of decayed wood, and these chemicals—are sources of the light called phosphorescence.

These are the sources of light the stars, the fire, electricity, friction, and phosphorescent substances. We can study the light from all of them, but the light from the sun or a lamp will be the most convenient. The light of the sun is the brightest and the cheapest light we can find, and is the best for our experiments. A good lamp is the next best thing, and in experimenting we will use either the sun or a lamp, as happens to be most easy and convenient.

The Heliostat.

In looking out of doors in the daytime we find that the sunlight fills all the air, and extends as far as we can see. It shines in at the window and fills the room. Even on a cloudy day, and in rooms where the sunshine cannot enter, the light fills everything, and is all about us on every side. Now, in studying light we do not wish a great quantity. We want only a slender beam, and we must bring it into a dark room, where we can see it and walk about it and examine it on every side, bend it, split it up into several beams, make it pass through glass or water, and do anything else that will illustrate the laws that govern it.

Choose a bright, sunny day, and go into a room having windows through which the sun shines. Close the shutters, curtains and blinds, at all the windows save one. At this window draw the curtain down till it nearly closes the window, and then cover this open space with a strip of thick wrapping-paper. Cut a hole in this paper about the size of a five-cent piece, and at once you will have a slender beam of sunlight entering the hole in the paper and falling on the floor. Close the upper part of the window with a thick shawl or blanket, and, when the room is perfectly dark, our slender beam of light will stand out clear, sharp, and bright.

As soon as we begin to study this beam of light, we find two little matters that may give us trouble. The sun does not stand still in the sky, and our beam of light keeps moving. Besides this, the beam is not level, and it is not in a convenient place. We want a horizontal beam of light, and some means of keeping it in one place all day. An instrument that will enable us to do this, and that can be adjusted to the position of the sun in the sky at all seasons of the year and every hour of the day, may be readily made, and will cost only a small sum of money.

---

[1] From a forthcoming volume of the "Nature Series"—"Light: a Series of Simple, Entertaining, and Inexpensive Experiments in the Phenomena of Light, for the Use of Students of Every Age," by Alfred M. Mayer and Charles Barnard.

We give several drawings giving different views of such an instrument and some of its separate parts. It is called a heliostat, and we shall find it of the utmost value in our experimenting in light, heat, sound, electricity, and other branches of physical science.

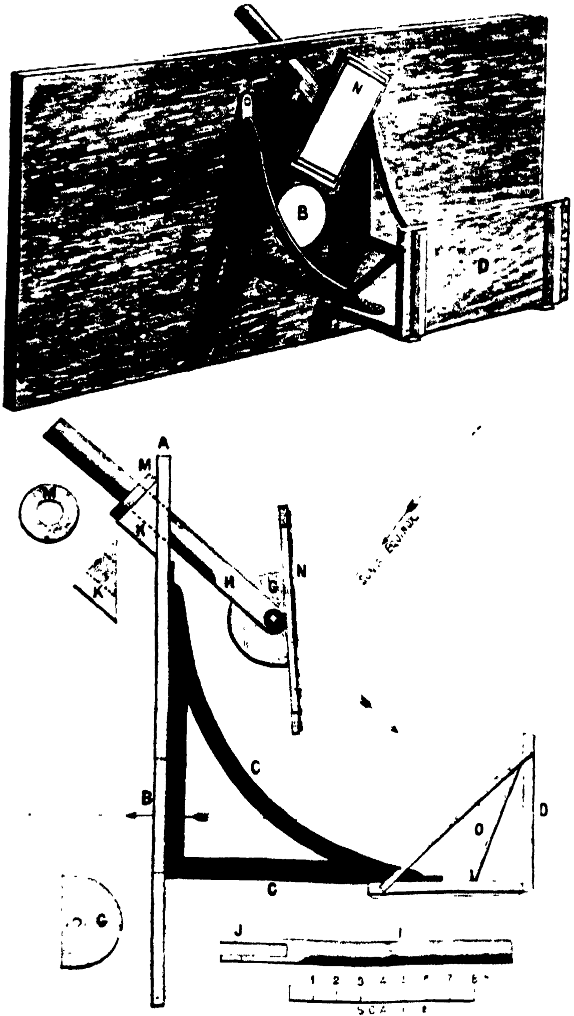

Fig. 1.

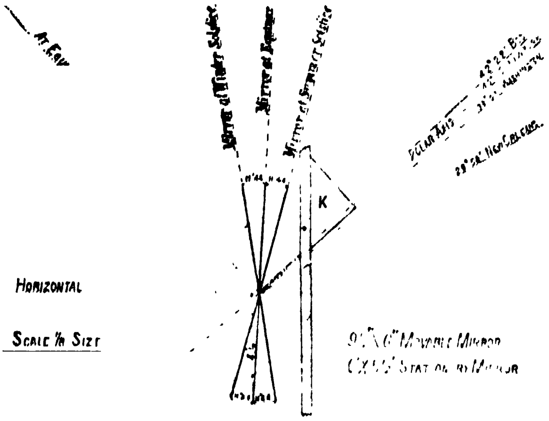
The first drawing represents a front-view of the heliostat. The second drawing gives an end-view, and we can now make one by simply following these few directions: The part marked A in the two drawings is a piece of pine board, 23 inches (58·4 centimetres) wide and two or more feet long, or as long as the window where it is to be used is wide. Any boy who can use plane and saw can make this piece of work out of common inch-board, and, if you have no pieces so wide as that, it can be made of two or more pieces fastened together with cleats; but, in this case, all the cracks must be close and tight. In the middle of this board, cut a round hole 5 inches (12·7 centimetres) in diameter, with its centre 8 inches from the bottom of the board. In the first drawing this hole can be seen at B, and in the second drawing it is shown by dotted lines at B. On one side of the board screw two iron brackets, using brackets measuring 14 inches (35·5 centimetres) by 12 inches (30·5 centimetres). These brackets are placed one on each side of the hole in the board, and are placed 14 inches (35·5 centimetres) apart, and with the short arm of the bracket against the board. In the first drawing the two brackets are shown, and in the second drawing one is shown in profile, and they are marked C in both drawings. On the end of the brackets is placed a flat piece of board, 6½ inches (16·5 centimetres) wide and 14 inches (35·5 centimetres) long, or long enough to reach from one bracket to the other. This board may be screwed up to the brackets, and thus make a shelf. Care must be taken in fastening this shelf to the brackets to place it so that the outside edge of the shelf will be 16 inches (40·6 centimetres) from the large board. On the outside edge of this shelf another board, 7 inches (17·8 centimetres) wide, is placed upright, and secured with screws and small strips of wood at the ends, as in the drawing. This shelf, with the wooden back, is marked D in the drawings.

These things make the fixed parts of the heliostat, and we have next to make the movable parts, or the machinery whereby it can be adjusted to the movement of the sun in the heavens. First, get out a flat piece of board 10½ inches (26·7 centimetres) long, 6¼ inches (16 centimetres) wide, and ½ inch (12 millimetres) thick. Then make a flat, half-round piece, shaped like the figure marked G. This piece must be ¼ inch (7 millimetres) thick, 5½ inches (14 centimetres) along the straight side, and with the circular part with a radius of 3 inches (7·6 centimetres). A hole, ½ inch (12 millimetres) in diameter, is made in this, as represented in the drawing, and then the half-round piece must be screwed to the flat piece of wood we just cut out. In the part marked N in Fig. 1 you will see these two pieces fastened together. The piece marked I is the most difficult piece of all. It should be made of ash or some hard wood. One end is square, and has a deep slot cut in it; the rest is round, and may be 1¼ inch (32 millimetres) in diameter. The square part must be large enough to slip over the half-circular piece, G, as is shown at H. A hole, ½ inch (12 millimetres) in diameter, is cut in the two ends, as marked by dotted lines at J, and through these holes an iron bolt and nut are fitted, so as to hold the circular piece, G, and yet allow it to turn freely in every direction. A hole, 1¼ inch (32 millimetres) in diameter, is cut through the triangular piece of wood K, as shown by the dotted lines, and then this block is securely fastened to the back of the large board, as shown in the second drawing. An opening of the same diameter, and having the same direction, is also cut through the board, and the movable piece, marked I, is put through this hole, as in the drawing. Finally, we want a wooden washer, 3½ inches (8·7 centimetres) wide, as represented at M. This we slip over the long wooden handle, as shown in the second drawing, and this washer rests on the block K, the top of which is 3½ inches square. This makes all the movable parts of the heliostat, and, when we have put in the mirrors, the instrument is finished and ready for use. We must have two mirrors, one 6 inches (15·2 centimetres) square and one 10 inches (25·4 centimetres) long and 6 inches (15·2 centimetres) wide. These may be made of common looking-glass: but plate-glass with silvered back is far better, and costs only a little more.

Any carpenter can make this instrument, and the cost will be about as follows: Wood, 50 cents; labour, $1.75; glass, $1; iron nut, 5 cents; brackets, 50 cents—total, $3.80. When finished, the instrument should have a coat of shellac-varnish, and, when this is done, the mirrors may be put in place, and fastened on with very heavy bands of rubber. This will enable us to take the glasses off when the instrument is not in use, and if the elastic bands or rings are very strong, they will answer perfectly. The long mirror is to go on the movable piece at N, and the small mirror stands on the shelf, facing the opening in the board, at O. This mirror stands at the angle shown in the next drawing (Fig. 2), and the other mirror is adjusted to the sun at its various positions in the sky at different seasons of the year.

Here is a diagram showing the position of the handle of the heliostat, and the mirror for different seasons and in different parts of the country. The handle must be placed on a line parallel with the axis of the earth, and the four dotted lines give its position when the heliostat is to be used in Boston, New York, Washington, and New Orleans. This also causes the block of wood marked K to have a slightly different shape, so that the hole through it will be in the middle. The dotted line marked "At Equinox" shows the path of the light from the sun, and the three dotted lines show the paths of the reflected light as it passes from one mirror to the other. The position of the movable mirror is also shown in the positions it has at the summer and winter solstices.



First Experiment with the Heliostat.

Choose a bright sunny day, and take the heliostat into a room having a window facing the south. Raise the sash and place the instrument in the window, and fasten it there so that it will be firm and steady. Before closing the window down upon it, move the larger mirror on its axis till it reflects a beam of light into the small mirror. Then turn the handle to the right or left, and a round, horizontal beam of light will enter the room. When this is done, close all the windows, so as to make the room as dark as possible. To do this, shawls or blankets or enamelled cloth will be found useful inside the curtains and shutters. Then get a piece of cardboard, about 6 inches (15·2 centimetres) square, and lay a five-cent piece in the centre, and, with a knife, cut a hole in the card just the size of the coin. Then fasten this, with pins or tacks, over the opening in the heliostat.

We have now a slender beam of light in a dark room. Walk about and study it from different sides. See how straight this slender bar of light is; it bends to neither the left nor the right, but extends across the room in an absolutely straight line. As the sun moves, turn the handle of the heliostat to keep the light in place.

Here (Fig. 3) is a picture of a dark room, in the window of which is the heliostat. In the centre of the piece of cardboard is the small hole where the light enters the room. A boy is holding one end of a long piece of linen thread just at the bottom of the hole in the card, and another boy has drawn the thread out straight and tight, so that it just touches the beam of light throughout its length.

Were you to try this experiment, you would see that the thread would suddenly be lighted up throughout its whole length, and would shine in the dark room like silver. Then if the boy allows the thread to become slack and loose, or if he lowers it even a very little, it will disappear in the darkness. If he raises and lowers it quickly, it will seem to appear and disappear as if by magic.

This is a very pretty experiment; but we must not stop to look at its merely curious effects. Try it over several times, and see if it does not show you something about the beam of sunlight. Plainly, if the thread is lighted up its whole length when it is straight, then the beam of light must be straight also. Here we discover something about light; we learn that it has a certain property. Our experiment shows that light moves in straight lines.

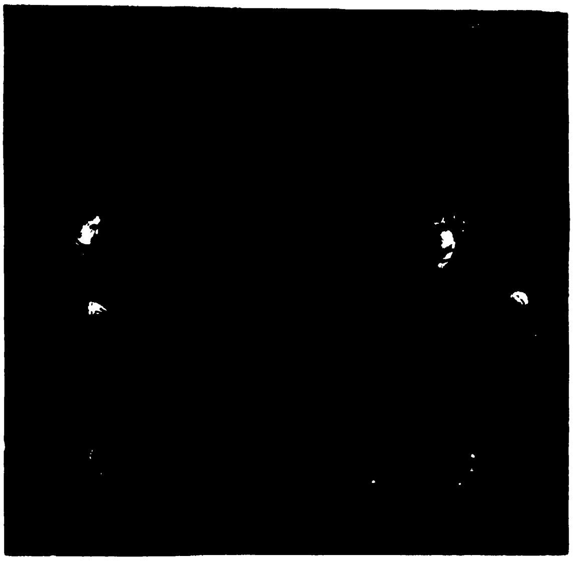


FIG. 3.

Experiment with Cards and a Lamp.

Here (Fig. 4) is a picture representing three little wooden blocks placed in a row upon a flat, smooth table, and fastened to them are three postal-cards, so that they will stand upright. At the end of the table is a small lamp. This is all we need to perform another experiment, that will show us the same thing we observed with the beam of light from the heliostat. To make these things, get a piece of wood 10 inches (25·4 centimetres) long, 3 inches (76 millimetres) wide, and 1½ inch (37 millimetres) thick, and saw it into 5 pieces, each 2½ inches (64 millimetres) long. Next make three slips of pine, 4 inches (10 centimetres) long, 3 inches (76 millimetres) wide, and ⅙ inch (4 millimetres) thick. Having made these, get three postal-cards, and lay them flat on a board, one over the other. Just here we need a tool for making small holes and doing other work in these experiments; and we push, with a pair of pliers, a cambric needle into the end of a wooden penholder or other slender stick, putting the eye-end into the wood, and thus making a needle-pointed awl. Measure off one-half inch from one end of the top postal-card, and with the awl punch a hole through them all, just half-way from each side. Lift the cards up, and with a sharp penknife pare off the rough edges of the holes, and then run the needle through each, so as to make the holes clean and even.

Take one of these cards and one of the wooden slips, and put the card squarely on one of the wooden blocks and place the slip over it, and tack them both down to the block. This will give us the cards and blocks as shown in the picture. When each card is thus fastened to a block, we shall have two blocks left. These we can lay aside, as we shall need them in another experiment.

Now light the lamp, and place one block on the table, quite near the lamp. Look at the lamp carefully, and see that the flame is just on a level with the hole in the card. If it is too high or too low, place some books under it, or put the lamp on a pile of books on a chair near the table. Take a chair and sit at the opposite end of the table, and place another card before you. Now look, through the hole in this card, at the first card before the lamp. If the table is level, you will see a tiny star or point of light shining through the holes in the two cards. Without moving the eye, draw the third card into line between the others, and in a moment you will see the yellow star shining through all three cards.

Next take a piece of thread and stretch it against the sides of the three cards, just as they stand, and immediately you see that they are exactly in line. The holes in the cards we know are at the same distance from the edges of the cards, and our experiment proves that the beam of light that passed through all the holes must be straight, or we could not have seen it. The cards are in a straight line, and the beam of light must also be straight. This experiment, like the first, shows us that there is a law or rule governing the movement of light, and that law is, that light moves in straight lines.

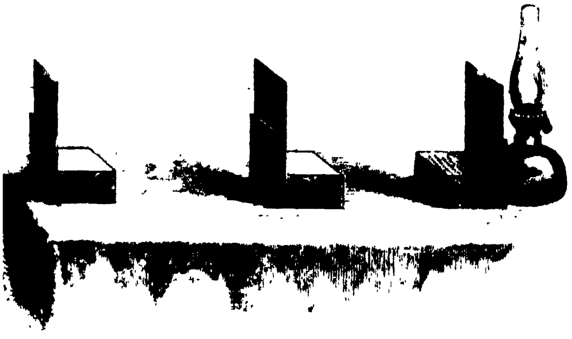

Fig. 4.

Move the lamp as near to the edge of the table as possible, and then bring one of the cards close to the lamp chimney. Then change your seat, and repeat this experiment several times in different directions. Each time you will see exactly the same thing, no matter in what direction the light moves from the lamp. The lamp may be moved from one side of the table to the other, and in every direction we shall find the light moving in exactly straight lines from the source of light. This is true whether the source be the sun, a lamp, or a star. One can walk all about the lamp and see it from every side, and we can place our three cards in any direction, north or south, up or down, east or west, or in any and every direction, and every time it will give the same result.

Thus we have found out the law by which light moves, viz., it moves in straight lines in all directions from the source of light.

Knowing this, you can readily think of a number of things in which these laws are made useful. A farmer planting an orchard, an astronomer fixing the positions of stars, a sailor steering his ship by night, employs this law: the first, to arrange his trees in straight lines; the second, to measure out vast angles in the sky; and the third, to lay the courses of his ship in safety. Each employs these laws with certainty and safety, because they are fixed and never change.

OUR ASTRONOMICAL COLUMN

Double Stars.—Vol. xliii. of the *Memoirs of the Royal Astronomical Society* contains two series of micrometrical measures of double stars. The first, by Mr. Knott, includes measures taken near Cuckfield, Sussex, between the years 1860 and 1873, with a refractor by Alvan Clark, having an aperture of 7⅓ inches, one of the instruments formerly in the possession of the Rev. W. R. Dawes. Measures of most of the well-known binaries will be found in this series, as also of a number of objects not so frequently under observation. Amongst the latter is the suspected variable, U Tauri, which has been observed on several occasions since November, 1863; D'Arrest first pointed out that this star, supposed to be variable by Mr. Baxendell, is really double; it is included in Schönfeld's last catalogue of suspicious objects with the query, "welche Componente veränderlich?" Mr. Knott's observations throw no light on this point, as he appears to have failed to notice any certain traces of change. A note referring to a star near β Leonis deserves attention. Smyth, in his *Cycle of Celestial Objects*, gives a measure, or, as it should perhaps be termed, an estimation of the position of a companion to this bright star, which he calls an eighth magnitude, and *dull red*, position 114°, distance 298″. At the epoch 1864·38 there was no star of such magnitude in this place, but Mr. Knott measured one which by the method of limiting apertures was found to be 11·6m., position 115°·4, distance 303″·5. The inference, especially in presence of Smyth's judgment of the colour of his companion, must be that we have here a new variable star. The *Durchmusterung* has nothing in this position.

The other series of double star measures to which we have referred emanates from the Temple Observatory, Rugby, and forms the second catalogue issued by Mr. Wilson and Mr. Seabroke. The previous catalogue was printed in the preceding volume of the *Memoirs*, and contains some introductory remarks that are wanting in the present one. The selection of objects and the instrumental means appear to be the same; the stars are found either in the Dorpat Catalogue or in the Pulkowa Catalogue of 1850. Amongst them may be noted O.Σ. 298, the first measures of which by the discoverer gave, for 1846·49, position 183°·8, distance 1″·19, while the Temple Observatory measures, 1873·48, assign for the position 232°, with an estimated distance, 0″·45, and the intermediate measures by Baron Dembowski, in 1866, confirm the change in angle and distance. A great change is remarked in Σ 651; at the epoch 1829·67 we have, position 101°·8, distance 10″·82, whereas the Rugby measures give for 1875·18, position 59°·3, distance 16″·26. In this case it is probable that the alteration is caused by proper motion of one of the components: thus the measures may be reconciled, if we suppose an annual motion of the principal star of about 0″·243 in the direction 17°·9. Of 32 Orionis it is remarked "not divided, perhaps binary," and the angle for 1874·1 is 198°·5; between 1830 and 1853 the distance appears to have been about one second without any decided change in the position, which by a mean of Struve, Dawes, and Jacob was 203°·6; the star seems to require further attention. Of 33 Pegasi, another object measured at Rugby, Struve remarks "comes in cœlo prorsus quiescit," or in other words the change in angle and distance noted between his measures in 1829 and 1851, is due to the proper motion of the principal star, which, according to Mädler, amounts to 34″·0 in the century, in the direction 93°·5. Mr. Wilson's measures of O.Σ. 311 confirm the marked diminution of distance mentioned by Dembowski in *A.N.* 1823—proper motion of one component is no doubt here also the cause of change.

These catalogues of double-star measures made at the Temple Observatory are meritorious productions from an institution not exclusively devoted to a regular course of observations, but also occupied in endeavouring experimentally to interest the youths of the school in astronomical science, with the hope that some, to use the words of the last Annual Report of the Royal Astronomical Society, "may hereafter join that band of amateurs to whom is owing much of what is most characteristic of English astronomy."

While referring to this Report it occurs to us to mention an article by O. Struve on the Baron Dembowski's long series of measures of double stars which is not noticed in the address of the President of the Society, on the occasion of the richly-merited award of the gold medal to the Italian astronomer. It is published in vol. viii. of the *Vierteljahrsschrift der astronomischen Gesellschaft*. After a general outline of the Baron's work, there is given an index to the volumes and numbers of the *Astronomische Nachrichten*, in which his measures have appeared, and which, though not entering into much detail, is useful in their present scattered state. Is it too much to hope that eventually the results of the indefatigable Gallarate observer, may be presented in a collective form, at least as regards their annual means?

SCHMIDT'S LUNAR CHART.—It is understood that this great work, which has been engraved at the expense of the Prussian Government, will, with accompanying letter-press description, be ready for issue in the course of a few weeks. We believe Prof. Auwers, of Berlin, is superintending its publication.

TEMPEL'S COMET OF SHORT PERIOD (1873 II.)—It is probable that the period of revolution of this comet, determined by Mr. W. E. Plummer, from observations extending from July 3 to October 20, will not be found to require very material correction; according to his orbit, the comet cannot attain the distance of Jupiter in its aphelion, and as at the last passage through this point, the planet was distant from it 7·70 (the earth's mean distance = 1) perturbations during the actual revolution are likely to be small. Assuming, then, with Mr. Plummer, that the revolution occupies 1,850 days, the comet may again arrive at perihelion about July 19·5 in the present year. Reducing the perihelion and node to 1878·0, we have the following expressions for the comet's heliocentric co-ordinates referred to the equator:—

$$x = r\,[9\cdot99212]\,\sin\,(v + \;\;30^\circ\,51'\cdot8)$$
$$y = r\,[9\cdot98170]\,\sin\,(v + 310^\circ\;\;7'\cdot9)$$
$$z = r\,[9\cdot53313]\,\sin\,(v + 274^\circ\,53'\cdot1)$$

Combining the co-ordinates thus found with the X, Y, Z of the *Nautical Almanac*, and taking July 19·5 for the time of perihelion passage, the following apparent track results:—

12h. G.M.T.

	Right Ascension.	North Polar Distance.	Distance from Earth.
	° ′	° ′	
April 20	281 1	95 56	1·025
May 20	297 53	93 50	0·708
June 19	316 7	95 12	0·488
July 19	334 42	104 56	0·370
August 18	347 22	118 45	0·307

The comet would be nearest to the earth on July 29, and brightest about that date. With such a course it should be well observed. Though, possibly, observations may have been made later than October 20 in 1873, so far as we know none such have been published. Mr. Plummer's elements will be found in the *Monthly Notices* R.A.S. for December, 1873.

[Since the above was written, we learn that Herr Schulhof is engaged upon this comet, with the view to providing an ephemeris for the approaching appearance.]

GEOGRAPHICAL NOTES

AMERICAN LONGITUDES.—The United States Hydrographic Office is continuing the work of establishing secondary meridians of longitude by the electric telegraph. Lieut.-Commander F. M. Green, U.S.N., with the same officers who have been engaged in similar work in the West Indies for some time past, has commenced the determination of South American meridians by measuring from the Royal Observatory at Lisbon through the cables of the Brazilian Submarine Company to Madeira and St. Vincent. The measurement will be continued by way of Pernambuco to Bahia, Rio de Janeiro, Buenos Ayres, and Valparaiso. The longitude of the Royal Observatory at Lisbon will shortly be determined with great exactitude by electrical measurement from London and Paris. The expedition has met with the most gratifying and cordial assistance from the officers of the Portuguese Government and the authorities of the telegraph companies.

NEW GUINEA.—The statement that gold has been discovered in New Guinea by Mr. Goldie, a plant-collector sent out by Messrs. Williams and Co., has caused considerable excitement in the Australian Colonies, but a letter in yesterday's *Times*, from the Rev. W. G. Lawes, who has just returned from a three years' residence on the south-east coast, ought to make would-be gold-hunters cautious. As yet the metal has been found in almost infinitesimal quantities, and we heartily support Mr. Lawes' recommendation that Government ought to take some means to prevent a rush of adventurers who would be sure to demoralise the people, and change to hostility their present decidedly friendly disposition towards white men. It is for the interests of the scientific exploration of the country that this friendly disposition should be maintained. We may state that Mr. C. S. Wilkinson, Government Geological Surveyor of New South Wales, inferred two years ago, from the rock specimens brought back by Mr. Macleay, that gold would probably be found in New Guinea, but he refrained from publishing the fact, he states, fearing it might cause a rush. Mr. Wilkinson states that gold is not likely to be found more plentifully in New Guinea than in the vast auriferous formations of New South Wales.

AFRICAN EXPLORATION.—Dr. Emin Effendi, who in 1876 travelled with Gordon Pasha to the Somerset River, sends from Mruli to Dr. Petermann, a sketch dated November last, of his second journey from Magungo on the Albert Nyanza, across Kirota and Masindi to Mruli in August last, and from Mruli to Mpara-Njamoga, in the south of Masindi, and back to Mruli (in September and October). Sir Samuel Baker, it will be remembered, found Kaba Rega, the lord of Ungoro, utterly intractable; but Dr. Emin Effendi spent a month alone with him, showing the impossibility of anticipating the chances of such travels. In November Dr. Effendi was to go from Mruli to Uganda and Karague, and thence, according to Gordon Pasha's desire, to reach, if possible, Lake Akanyaru, the Mfumbiri Mountains, and Ruanda.

ARCTIC EXPLORATION.—The U.S. Senate has passed the Bill for allowing the *Pandora*, which has been chartered by Mr. James Gordon Bennett for an Arctic Expedition, to sail under the American flag, and for permitting United States naval officers to be detailed for service on board that vessel during the proposed expedition.

PETERMANN'S MITTHEILUNGEN.—As a sequel to a former paper on the distribution of the sedimentary formations of Europe, Petermann's *Mittheilungen* for March contains another on Europe during the two glacial periods, accompanied by a map. The paper on the distribution of palms is concluded, and the first instalment of a summary of exploration of the Ogové given, accompanied by a map.

The April part will contain a long paper, with map, by Prof. Hertzberg, on the Ethnology of the Balkan Peninsula in the fourteenth and fifteenth centuries, and the conclusion of the paper on Prof. Nordenskjöld's proposed expedition from Norway to Behring's Straits. There is also the itinerary (with map) of a journey between Ozaki, Kioto, Nara, and Ominesanjo, in Nippon, Japan, by Dr. Knipping.

AMERICAN GEOGRAPHICAL SOCIETY.—In the *Bulletin* of the Society, No. 5 (1876-7) will be found a pretty full account of the work of the American Palestine Exploration Society, by Dr. Merrell, and a paper on a trip up the Magdalena, and among the Andes, by Mr. J. A. Bennett, U.S. Consul at Bagotá. At the meeting of the society on February 27, the president, Chief-Justice Daly, gave his annual address, summing up in an interesting and complete manner the geographical work of the past year.

BERLIN GEOGRAPHICAL SOCIETY.—The fiftieth anniversary of the foundation of this Society will be celebrated in the Kaisersaal of the Flora. The Crown Prince of Germany, several ministers, and numerous foreign guests, are expected to be present at the festival, which will begin on April 31. The last three numbers for 1877 of the *Verhandlungen* of this Society contain some papers which may interest geographers and ethnologists. Among these (in No. 8) are a paper by Prof. Virchow on "The Anthropology of America," and in the same number a paper on "The Hygiene of the Tropics," by Herr Falkenstein; in No. 10 a paper by Dr. Hildebrandt on his travels in East Africa, in his attempt to reach Mounts Kenia and Kilima-Njaro, to which we have already referred.

SUMATRA.—The Dutch Geographical Society has recently received important news from the Expedition in Sumatra. MM. van Hasselt and Veth report that in the course of their exploration of the southern highlands of Padang, they ascended the Peak of Indrapura, the highest mountain in Sumatra. From the summit of this volcano they had an extensive view over the land and lakes of Korintji. The travellers also report that of late they had met with less enmity on the part of the independent chiefs than at the outset of their expedition.

NOTES

DURING the field operations of one of the parties connected with the U.S. Geological Survey of the Territories, in charge of Prof. F. V. Hayden, portions of south-western Colorado, north-western New Mexico, and north-eastern Arizona, were traversed, embracing that broken-up country occupied in remote times by a race of people who were known as the cliff-dwellers. This subject is well known to readers in general, but we must recur to it again so as to be able to reach the importance of the discovery to be described. In one of the cañons, known as the Chaco, Mr. H. W. Jackson made detailed investigations and measurements of the immense ruined buildings. In one of the arroyas or dry water-courses, the sectional view of the alluvial deposit was exposed to a depth of about sixteen feet. Fourteen feet beneath the surface, a layer of pottery and *débris* came to view. This may not seem strange, as, in a comparatively narrow valley, dirt and gravel to the depth of fourteen feet might be deposited in a short term of years. But ten feet above this layer the foundation walls of ancient buildings were visible, built upon another layer of gravel and sand. These were in time covered with the alluvium upon which now stand the famous ruins, of which no history is extant, and of the builders of which no history will ever be known. How many ages have passed since the lower or first bed was the surface upon which moved the numerous hordes, of which all evidence at present is hidden behind the veil of the dark past? Now, a skull comes to view upon the layer of pottery, which is beneath two eras of occupation and semi-civilisation. This skull, in its contour, is unique. Its closest relations are the ancient Mexicans, Peruvians, Caribs, and Natchez. There is an extraordinary flattening of the upper posterior portion of the head (posterior parietal), which is evident in those figured in Morton's *Crania Americana*. The contents of the skull as found, consists of sand, which is now as hard as ordinary agglutinated sandstone, and has, in nearly all portions, the appearance of liminite. The skull will be described and figured by Dr. W. J. Hoffmann, of the U.S. Survey, and it affords another strong link in the chain of facts and hypotheses of the cliff-dwellers and the ancient Mexicans being more nearly related than is generally admitted or supposed.

MR. PARK HARRISON telegraphs to us from Worthing that he has just (yesterday) exhumed, at Cissbury, a contracted skeleton, sixteen feet deep, lying in the centre of the pit, over which the cist was found last autumn. The work will be continued on Saturday and next week.

A SCRUTINY took place on the 18th instant at the Academy of Sciences for the nomination of a successor to M. Leverrier as member of the section of astronomy. The successful candidate was M. Tisserand, the Director of Toulouse Observatory, who took thirty-two votes out of fifty-five, against M. Wolf. M. Tisserand was the second astronomer of the Japan Mission for the Transit of Venus, which was led by M. Janssen.

As we have already stated, a subscription list has been opened in France for the foundation of a memorial to Claude Bernard. A small sub-committee has been formed to obtain subscriptions in this country, consisting of Sir James Paget, Dr. J. Burdon Sanderson, Prof. Humphry, Dr. Michael Foster, Mr. Ernest Hart, Mr. Romanes, and Prof. Gerald Yeo, King's College, to the latter of whom, as honorary secretary of the Physiological Society, subscriptions may be sent.

PORTER AND COATES of Philadelphia are about to bring out a new and cheap edition of Wilson and Bonaparte's "American Ornithology," three volumes in one, together with 103 new plates.

THE report of Major Feilden, the naturalist of the Arctic Expedition, is now nearly completed, and will shortly make its appearance as a Parliamentary Paper, together with some interesting additional remarks by Sir George Nares.

GENERAL DE NANSOUTY published in the beginning of March a letter stating that a sum of 20,000 francs was required to complete the Pic-du-Midi Observatory, of which he is director. Three days after the publication of his letter in the *XIXme Siècle*, an inhabitant of Calais sent him 5,000 francs, and five days later he was presented with a sum of 15,000 francs by M. Bischofsheim, the eminent Parisian banker, whose generosities to science we have so often to record.

Brownea grandiceps is producing its fine *Rhododendron*-like heads of flowers in No. 1 house at Kew.

KING HUMBERT of Italy has granted four annual prizes of 5,000 lire each (about 190*l.*) for the best productions in art, science, and literature. The Academia dei Lincei, at Rome, is charged with the annual award and distribution of these prizes.

A COMPETITIVE trial of German and Swiss chronometers took place recently at the Deutsche Seewarte at Hamburg, by order of the German Admiralty. The best instrument was furnished by Herr Bröcking, and its performance is said to be superior to that of any chronometer examined at Greenwich during the last three years.

MAJOR-GENERAL SIR HENRY RAWLINSON, K.C.B., F.R.S., and Sir John Lubbock, M.P., F.R.S., have been appointed trustees of the British Museum in the place of the late Right Hon. Sir David Dundas and the late Sir William Stirling Maxwell.

THE death is announced of Dr. Joseph Henry Corbett, of Dublin. The deceased was formerly Professor of Anatomy and Physiology, and an Examiner in the Queen's University in Ireland.

WE understand that the herbarium of the late eminent botanist, Alexander Braun, has been purchased by the German Government for the sum of 21,000 marks.

THE cryptogamic herbarium of the late Italian botanist, G. De Notaris, has been acquired by the Italian Minister of Public Instruction for the Botanic Garden at Rome.

WE are happy to state that a decree has established in Lyons, in Bordeaux, and in Besançon observatories for astronomical, meteorological, and horological purposes. For the two former towns, and especially for Lyons, this decree is merely an acknowledgment and regulation of former efforts, but the merit of this measure is not lessened by that consideration, as it puts an end to all local opposition.

EASTER being very late this year, the meeting of the delegates of the French learned societies will take place in the last days of April, only three or four days before the opening of the International Exhibition.

AT a meeting at the Mansion House last week an influential committee was formed to promote the holding of a great agricultural exhibition in London next year, under the auspices of the Royal Agricultural Society of England. Hyde Park was proposed as the place for holding the show.

A SHOCK of earthquake is reported to have been felt at Debenham, a few miles from Ipswich, on Saturday morning.

THOUGH the cultivation in India of the best quinine-yielding species of Cinchona (*C. officinalis*) has not proved a success, it is satisfactory to know that one species at least thrives most abundantly in the Sikkim plantations. From a paper read at the last meeting of the Pharmaceutical Society by Mr. Wood, the Government Quinologist in India, it seems that out of a total of about three million trees, comprising four or five species of Cinchona it is estimated that there are as many as 2,500,000 belonging to the species *succirubra*. It is from this bark that the now well-known "Cinchona febrifuge" is prepared. This substance, according to many well known medical practitioners in India, possesses to so very nearly the same extent the anti-periodic properties of quinine that it may be safely substituted for the latter in the treatment of ordinary fevers and ague. 5,000 lbs. of this febrifuge, we are told, has already been made and issued, and it is now being made at the rate of 4,000 lbs. a year; the demand, however, is so rapidly overtaking this scale of production that a further extension will shortly be necessary. For use it appears in the form of a fine white powder, which, however, becomes in a short time of a pale buff tint. It does not agglutinate even in the Indian climate. It is freely soluble in weak acids and is readily taken up by lemon-juice, which constitutes a pleasant vehicle for its administration.

THE Pharmaceutical Society of Great Britain has just issued an excellent catalogue of the fine collections of Materia Medica and chemical products in their museum in Bloomsbury Square. The catalogue is the work of the Society's Curator, Mr. E. M. Holmes, F.L.S., and includes a great deal of information regarding the several products mentioned. The alphabetical classification of the plants according to their genera in each order and the numerous references to figures in English, American, and foreign works will make this book valuable not only to students of the collection it illustrates, but also for handy reference on the subject generally.

THOSE who are interested in the subject of railway brakes will obtain much instruction and pleasure by a visit to the offices of the Westinghouse Brake Company, at St. Stephen's Palace Chambers, Westminster, where the Company's Automatic Brake may be seen at work. By an ingenious arrangement the brake-power sufficient for a train of ten carriages is represented. At one view the whole of the apparatus that would be brought into play to bring such a train to a stop is seen. A steam-engine compresses the air and distributes it through all the tubes and the ten reservoirs extending over the whole length of the train, and which, by simply turning a handle, acts upon the brakes, one of which is ready to clasp each wheel of the train. The brake can be applied by engine-driver or guard in little more than five seconds, and its action is so powerful that a train going at forty miles an hour can be brought to a dead stop in something like fifteen seconds and within a distance of about 500 yards. The essential principle of this system is the admission of compressed air into a cylinder attached underneath a carriage, and containing the ends of two pistons acting by leverage upon the brakes; the compressed air is stored in pipes attached to the cylinder, and is thus ready for instantaneous admission, which is effected by producing a reduction of pressure, and thus opening a set of valves that admit the air into the cylinder. The air thus admitted acts upon the pistons by pushing them out and causing the brakes to clasp the wheels and instantly stop their revolution. The distinctive feature of the automatic brake is that in case of the train breaking into one or more parts or in case of its meeting with any obstruction or leaving the rails, the brakes are at once applied automatically, and thus the risk of disaster is immensely diminished. Our examination of the apparatus has convinced us of its perfect efficiency, which we find is testified to by all the railway companies that have used it; and any one who has recently travelled north by the Midland Railway must admit that it would be difficult to improve upon a system that can bring a long train going at full speed to a stop within a few seconds. The brake can be applied with any strength, and thus is of great service in going down inclines and taking sharp curves. On the apparatus at St. Stephen's Chambers is a nozzle from which the compressed air may be allowed to escape, and with which some curious phenomena with a hollow elastic ball are shown. The ball is placed within the current of escaping air, and if the tap is kept upright the ball is sustained as if by a jet of water, but with little or no revolving motion. If the tap be brought to an angle of say thirty or forty degrees from the perpendicular, the ball is still sustained by the current, receding and advancing in the line of the tap and revolving rapidly outwards in the direction of the current, so rapidly as to produce a most marked flattening at the poles or sides at right-angles to the direction of motion. Ultimately it becomes almost a disc. Gradually the axis of rotation changes till it is at right-angles to its original position, when the speed of rotation diminishes and the ball gradually comes to rest. Again it begins to spin upon its new axis, going through the same changes again and again so long as it is kept within the action of the jet. In concluson we may say the brakes are comparatively simple in construction; it is almost impossible to put them out of order, and they may be effectually handled by ordinary railway officials.

THE method of coincidences has recently been applied by M. Szathmari, to determine the velocity of sound in free air, as follows:—A pendulum, whose rate was accurately known, closed, at each passage through the vertical position, a battery circuit, the line of which was 220 m. long, and included two electric bells. When both bells are placed before the observer, he hears them simultaneously. If one be moved a little way off this simultaneity ceases; and if the bell be moved still further a point is reached, at which both bells are heard simultaneously again. The distance is that through which the sound moves in the interval between two successive ringings of the bells. The pendulum in the present case, had a period of 0·2961 seconds; the distances at which the sounds of the two bells were heard at once were directly measured, and the average value (from thirty measurements) was 99·25 m. From this the velocity of sound in free air = 335·19 m. Reducing the value to that for dry air at zero the number obtained is 331·57 m. This lies about midway between Regnault's value (330·7) and that of Moll and Van Beck (332·26).

AT a recent meeting of the Berlin Geographical Society, Prof. Karsten, of Kiel, read an interesting account of the activity of the Commission established in Schleswig-Holstein, which has for its object the exact and minute investigation of the climatological, physical, and chemical conditions of the Baltic and the German Ocean, as well as of the influence which these conditions exercise upon organic life. The commission has established a large number of stations for making observations of the currents existing in these seas, in order to obtain data for the understanding of the general laws governing marine currents. With regard to animal life, the commission has up to the present confined its labours to the most important inhabitant of the two seas, the common herring, and it has succeeded in determining with certainty the few zoological varieties of this fish, as well as in finding its spawning places, and as a result, the artificial cultivation of herrings has already been set on foot. The commission will now devote its attention to other species of fish.

A GERMAN Viticultural Society has just been formed at Cassel. For the present the Society intends to take up two important matters, viz., (1) discovering the best method for the destruction of phylloxera, and (2) the suppression of the secret manufacture of wines by artificial means.

IN NATURE (vol. xvii. p. 372) an account is given of the difficulty met with in Australia in getting bees to work after a few years. A correspondent calls attention to the fact that a similar difficulty occurred in California, where it has been obviated by a systematic abstraction of the honey as the bees collected it. If this were tried in Australia it might possibly meet the difficulty.

IN a recent communication to the Belgian Academy on digestion in insects, M. Plateau, after a careful examination of forty individuals of various types retires from his former position that the digestive juices (in the normal state) are *never acid*. In insects which feed wholly or partly on animal matters, they are slightly acid. He will not, however, concede a constant acidity for all insects (which some naturalists affirm); and in reply to the objection based on the characteristic acidity of the gastric juice of vertebrates, he contends that the digestive liquid in articulata, insecta, myriapoda, arachnida, and crustacea is not analogous to that juice, but rather to the pancreatic juice; the acidity is an accessory character and not the sign of a physiological property. The ferment present is evidently something quite different from the gastric pepsine of vertebrates. Thus, a very little hydrochloric acid, so far from promoting its action, retards or arrests it.

A NEW method, said to be more accurate in its results than that of Helmholtz, for determining the tones of the mouth-cavity which correspond to the vowels, is recommended by M. Auerbach in a recent number of the *Annalen der Physik*. It is based on percussion. Having made a long inspiration, you bring the mouth into the position corresponding to the particular vowel, and then strike the larynx after the manner of physicians, *i.e.*, place the middle finger of one hand firmly on it, and strike it with that of the other hand. A comparatively distinct tone is then heard, which varies with the position of the mouth, but for a given position is always the same. The effects are perceived more distinctly if the ears are previously stopped with wax. M. Auerbach describes results of observation by this method.

MR. A. W. BENNETT (Lecturer on Botany, St. Thomas's Hospital, London, S.E.) requests us to state that he is engaged on an introductory handbook of Cryptogamic Botany, to be published in the International Scientific Series, and that he will be extremely glad of any recent original memoirs, English or Foreign, bearing on any branch of the subject which the authors may incline to send him.

AN International Congress of Botany and Horticulture will be held in Paris on August 16 and following days, under the auspices of the Botanical Society and the Central Horticultural Society of France, in the rooms of the latter Society, 84, rue de Grenelle. A programme of subjects, botanical and horticultural, is announced, on which papers are especially invited, as well as the exhibition of illustrative specimens, collections, and apparatus. One of these subjects is the establishing and fitting up of botanical laboratories. The attendance and co-operation of foreign botanists are cordially invited.

IN the year 1877 no less than 8,000 new publications appeared in Italy. Amongst these there were 5,743 new books (1876 : 4,323), 1,880 pamphlets (1876 : 1,524), and 104 new journals (1876 : 256).

THE additions to the Zoological Society's Gardens during the past week include two Common Marmosets (*Hapale iacchus*) from South-East Brazil, presented by Mr. R. Donaldson; a Three-striped Paradoxure (*Paradoxurus trivirgatus*) from India, presented by Capt. Dalrymple; a Secretary Vulture (*Serpentarius reptilivorus*) from South Africa, presented by Messrs. W. Rigg and J. Curtis; a Green Glossy Starling (*Lamprocolius chalybeus*) from North-East Africa, a White-eared Bulbul (*Pycnonotus leucotis*) from India, a Californian Quail (*Callipepla californica*) from California, presented by Mrs. Arabin, F.Z.S.; a Common Kestrel (*Tinnunculus alaudarius*), European, presented by Mr. A. Blumenthal; a Lion (*Felis leo*) from Africa, a Variegated Sheldrake (*Tadorna variegata*) from New Zealand, received in exchange; two Common Swans (*Cygnus olor*), European, deposited; three Black Swans (*Cygnus atratus*), bred in the Gardens; a Zebu (*Bos indicus*), two Common Badgers (*Meles taxus*), born in the Gardens.

THE ANALOGIES OF PLANT AND ANIMAL LIFE[1]

II.

WE may find a kind of analogy for these cases of contradictory action—for they really strike one as contradictory.

The chameleon and the frog are both affected in a peculiar manner by light; they both change colour in accordance with variations in the intensity of the light. Moreover, the change of colour is produced by the same mechanism in the two cases; by a kind of contraction and expansion of certain coloured cells in their skin. But the curious fact is that chameleons[2] become darker in sunshine, while frogs[3] become pale in sunshine and darker in darkness. No doubt both these changes are in some way serviceable to the frog and the chameleon, and we may suppose that the whole phenomenon is really analogous to the opposite effects of light which occur in plants.

To quit the paths of science for those of another region of "Wonderland," it has been pointed out by Mr. Lewis Carrol that dogs wag their tails when they are pleased, whereas cats do so when angry. Seriously the principle is the same—given that emotion produces disturbance of the tail, it will depend on the surrounding circumstances in which the creatures live as to whether a given emotion shall produce a wagging or a rigid tail.

Let us once more consider what needs will arise in the life of an animal, and then see how the same needs are supplied by plants. An animal needs to be alert to changes going on in the world around it; it needs delicate sense-organs to perceive the approach of enemies or the whereabouts of its food. In fact it is evident that to prosper in the varying conditions of life an animal must be sensitive to these changes. By sensitiveness one means that an animal must be capable of being affected by changes which, considered as mere physical agents, are insignificant. A fly living in the same room with an active-minded boy will depend for its safety on its power of rapidly appreciating the approaching shadow of the boy's hand. Now the changes produced in the arrangement of forces in the universe are not perceptibly affected by this shadow—it is utterly insignificant—yet what a violent effect it has on the fly. It is because the nervous system of the fly possesses the property of magnifying external changes so that apparently slight disturbance causes large results.

---

[1] A Lecture delivered at the London Institution on March 11 by Francis Darwin, M.B. Continued from p. 391

[2] Brücke, *Wien. Denkschrift*, 1851; v. Bedriaga, "Die Entstehung der Farben bei den Eidechsen," 1874.

[3] Lister, Cutaneous Pigmentary System of the Frog. (*Phil. Trans.*, 1858; v. Wittich, Müller's *Archiv*, 1854.

This power of being strongly affected by apparently slight changes is a very important character of living matter. The processes which occur within the fly have been likened to the explosion of a pistol, the force used in moving the trigger being utterly insignificant when compared with the result produced. I do not mean that this exploding power is a distinguishing mark of living matter, but it certainly is a well marked feature. Besides the power of magnifying or intensifying external changes, which we have described as the exploding power of irritable tissue, there is another, the power possessed by nerves of transmitting a stimulus wave from one part to another. We will first look for this transmitting power as it exists in plants.

The leaf of the sundew, or Drosera, consists of a shallow, slightly saucer-shaped disc covered over with short glands, and fringed all round with projecting tentacles which also terminate in glands. The glands secrete a sticky fluid, which hangs in drops on them, hence the name of sundew, because the leaves seem to be covered with dew in sunshine, when other plants are dry. Insects are caught by the sticky secretion, and are also embraced and held fast by the outer tentacles, which possess the power of moving. When the insect has been killed by being drowned in the sticky secretion, it is digested by the acid juice poured out by the glands and subsequently absorbed.

The external or movable tentacles may be made to bend inwards, either by insects alighting on the centre of the disc of the leaf, or on the sticky glands of the tentacles themselves. In the first case, when an insect is caught on the middle of the leaf, and the external tentacles bend in and surround it, we have a true transmission of stimulus, a message sent, like a message is sent along a nerve. The insect may be struggling to free itself, and will probably succeed in doing so, unless the external tentacles give their help. The external tentacles can be made to bend not only by insects or other objects placed on the centre of the leaf, but also by anything placed on the gland at the end of the tentacle itself. In this case the meaning of the movement is equally obvious. If a gnat or fly lights on one of the external glands, it will probably escape, unless carried to the centre of the leaf, where it will be also held by the small sticky glands. Here also there is a true transmission of stimulus. The message has to be sent from the gland at the top to the place where the tentacle bends; a message is sent from the gland to the bending part of the tentacle, just as a message goes through nerve tissue from our skins to our muscle.

In this case the tentacle always carries the fly it has caught to the actual centre of the leaf. But if a fly has been caught by the disc of the leaf, and not quite in the centre, then the messages are sent in accordance with the position of the fly, and all those tentacles within reach move to the point of irritation with marvellous precision. This transmission of messages is all the more wonderful, because, as far as our powers of observation go, there is no special structure to convey the stimulus. It is true that waves of stimulation do travel with special facility along the fibro-vascular bundles, or what are usually called the veins of the leaf. But in this case, where tentacles converge to a given point in the disc of the leaf, this mode of transmission is impossible, because the veins are few in number, and could not cause so nice an adaptation of movements. Moreover, stimuli can travel across a leaf of Drosera after the vascular bundles have been cut through.[1] So that we have the wonderful fact of a wave of stimulation travelling with great accuracy transversely through a number of cells with absolutely no structure like nerve-fibre to guide the course in which the stimulus-wave shall flow.

One other curious phenomenon may be alluded to as showing the extraordinary power of stimulus transmission. If a piece of meat is placed on an external tentacle, the gland on which it rests sends forth an acid secretion; and if a piece of meat is placed on the centre of the leaf, the tentacles, as before said, bend in and ultimately touch it; but if the external glands are tested with litmus paper before they reach the meat in the centre, they will be found to be covered with acid secretion, proving that not only had a message been sent to the moving part of the tentacle, but also to the secreting cells in the gland.

One might find a parallel to this in the action of the human salivary glands. The gland nerves may be excited either by the stimulus of food placed in the mouth, or by the voluntary action of the muscles of mastication. Here the saliva is poured out, although there is no food to act on, just as the Drosera-gland secretes during the movement of the tentacle before there is anything for its secretion to digest.

Having briefly considered the transmission of stimulus-waves as shown in Drosera I will pass on to consider what manifestations may be found of the other general property of nerve tissue, the property which I have called exploding power. It is chiefly manifested in Drosera by the extreme sensitiveness of the glands on the external tentacles. It is found not to be necessary to place meat or insects on the gland, but that bits of glass, wood, paper, or anything will excite them. Smaller and smaller atoms were tried and still the glands were found to be sensitive to their presence.[1] At last a minute piece of a human hair, about one-hundredth of an inch in length, and weighing just over $\frac{1}{80000}$ of a grain, was placed on the gland of a tentacle and it caused unmistakable movement. The case is yet more wonderful than it sounds, because the piece of hair must be partly supported by the thick drop of secretion on the gland, so that it is probably no exaggeration to say that the gland can perceive a weight of one-millionth of a grain. This degree of sensitiveness is truly astonishing, it seems to us more like the sense of smell than that of touch, for to our most delicate tactile organ, the tongue, such atoms are quite imperceptible.

The power which Drosera has of perceiving the presence of ammonia is perhaps still more astonishing. A solution of phosphate of ammonia in pure distilled water in the proportion of one part to over two million of water, caused inflection of tentacles.[2] One may form an idea of this result by making a solution of a single grain of the phosphate and thirty gallons of distilled water, and then finding out that it is not pure water. Considering the water-supply which we at present enjoy, we may well be grateful that our senses are duller than those of a sundew.

As examples of simple sensitiveness these facts are sufficiently striking, but the powers of discriminating between different kinds of stimuli are equally curious. The tentacles having proved so extraordinarily sensitive to light bodies resting on them, one would expect that the slightest touch would make them bend. But it is not so; a single rapid touch, though it may be violent enough to bend the whole tentacle, does not cause inflection. The meaning of this is clear, for in windy weather the glands must be often touched by waving blades of grass, and it would be a useless labour to the plant if it had to bend and unbend its tentacles every time it was touched. It is not excited except by prolonged pressures or quickly repeated touches. This is also quite intelligible, for when an insect is caught on the sticky secretion of the gland it will give a somewhat prolonged pressure, or a number of kicks to the sensitive gland, unless indeed it flies away after a single struggle, and in that case the tentacle will be also saved from uselessly bending.

In another carnivorous plant, Dionæa, the specialisation of sensitiveness is exactly the reverse; thick and comparatively heavy bits of hair can be cautiously placed on the sensitive organs without causing any movement, but the delicate blow received from a cotton thread swinging against the hair causes the leaf to close.[3] Dionæa catches its prey by snapping on it like a rat-trap—there is no sticky secretion to retain the insect as in Drosera till the slowly moving tentacles can close on it. Its only chance of catching an insect is to close instantly on the slightest touch. The specialisation of sensitiveness in Dionæa is therefore just what it requires to perfect its method of capture.

In describing the sensitiveness of Drosera and Dionæa I wish rather to insist on a wide and general similarity to the action of nerves. There may be said to be an analogy between the specialisation of extreme sensitiveness in Drosera and Dionæa and the nervous tissues of animals, because these properties play the same part in the economy of the plant that is supplied through some kind of nerve machinery in the higher animals. Closer analogies could be pointed out. There are, for instance, the well-known researches of Dr. Burdon Sanderson, in which he compares the electrical disturbances which occur in the leaf of Dionæa to those which take place in nerve and muscle. Again Mr. Romanes has, in a recent lecture in this place, compared the peculiar sensitiveness of Drosera to repeated touches with the phenomenon known in animal physiology as the summation of stimuli. But I have merely sought to show that we find in Drosera a power of conduction of stimuli, an extreme sensitiveness to minute disturbances, and a power of discriminating between different kinds of stimuli which we are accustomed to associate with nervous action. To establish this analogy I believe that the examples already mentioned may suffice.

---

[1] See Batalin, "Flora," 1877, who has correctly pointed out the importance of the fibro-vascular bundles as conveying stimulus-waves.

[2] "Insectivorous Plants," p. 170.

[3] "Insectivorous Plants," p. 289.

We will now inquire whether among plants anything similar to memory or habit, as it exists among animals, may be found.

The most fruitful ground for this inquiry will be the phenomenon known as the sleep of plants. The sleep of plants consists in the leaves taking up one position by day and another at night; the two positions for night and day following each other alternately. The common sensitive plant (Mimosa) is a good example of a sleeping plant. The leaf consists of a main stalk from which two or more secondary stalks branch off; and on these secondary stalks are borne a series of leaflets growing in pairs. The most marked character of the night or sleeping position is that these leaflets, instead of being spread out flat as they are in the day, rise up and meet together, touching each other by their upper surfaces. At the same time the secondary stalks approach each other and ultimately bring the rows of closed-up leaflets (two rows on each stalk) into contact. Besides this well-marked change the main stalk alters its position. In the afternoon it sinks rapidly, and in the evening it begins to rise, and goes on rising all night, and does not begin to sink until daylight. From that time it sinks again till evening, when it again rises, and so on for every day and night. In reality the movement is more complicated, but the essential features are as I have described them.

In comparing the sleep of plants with anything that occurs in animal physiology, we must first give up the idea of there being any resemblance between this phenomenon and the sleep of animals. In animals, sleep is not necessarily connected with the alternation of light and darkness, with day and night. We can imagine an animal which by always keeping its nutrition at an equal level with its waste would require no period of rest. The heart which beats day and night shows us that continuous work may go on side by side with continuous nutrition.[1] Mr. Herbert Spencer has suggested that since most animals are unable to lead a life of even ordinary activity during the night because of the darkness, therefore it answers best to lead an extremely active life in day when they can see, and recover the waste of tissue by complete rest at night. On the other hand, certain animals find it more to their profit to sleep in the day and rest at night. But there is nothing of this kind in plants; their sleep movements are not connected with resting. Although the leaflets close up, yet the main stalk is at work all the night through.[2] Moreover, owing to the closing up of the secondary stalks of the leaf, the length of the whole organ is increased, and therefore the work done by the main stalk is also increased. So that, far from resting at night, the main stalk is actually doing more work than in the day. Besides this, instead of being more or less insensible, as a sleeping animal is, the primary petiole of the Mimosa remains fully sensitive at night, and displays the same property which it shows by day, viz., that of falling suddenly through a large angle on its irritable joint being touched. Besides these points of difference, there is the important distinction that the movements of sleeping plants are strictly governed by light and darkness without any reference to other circumstances.

In Norway,[3] in the region of continual day, the sensitive plant remains continually in the daylight position—although no animals probably remain continually awake.

There is one—but only a fanciful resemblance—between the sleeping plants and animals, namely, that both have the power of dreaming. I have been sitting quietly in the hot-house at night waiting to make an observation at a given hour, when suddenly the leaf of a sensitive plant has been seen to drop rapidly to its fullest extent and slowly rise to its old position. Now in this action the plant is behaving exactly as if it had been touched on its sensitive joint; thus some internal process produces the same impression on the plant as a real external stimulus. In the same way a dog dreaming by the fire will yelp and move his legs as if he were hunting a real instead of an imaginary rabbit.[1]

I said that in the regions of perpetual light the sensitive plant remains constantly in the day position. We might fairly expect, therefore, that we should be able to produce the same effect by artificial light constantly maintained. This experiment has, in fact, been made by A. de Candolle,[2] Pfeffer, and others with perfect success. But before the leaves come to rest a remarkable thing takes place. In spite of the continuous illumination, the sleeping movements are executed for a few days exactly as if the plant were still exposed to the alternation of day and night. The plant wakes in the morning at the right time and goes to sleep in the evening; the only difference between these movements and those of a plant under ordinary circumstances is that under constant illumination the movements become gradually smaller and smaller, until at last they cease altogether. When the plant has been brought to rest it can be made to sleep and wake by artificial alternations of darkness and light. This fact seems to me extremely remarkable, and one which, in the domain of animal physiology, can only be paralleled by facts connected with habit. The following case is given me by a friend and is probably a common experience with many people:—Having to be at work at a certain time every day, he has to get up at an early hour, and wakes with great regularity at the proper time. When he goes away for his holiday he continues for a time waking at the proper hour to go to work, but at last the body breaks through the habit, and learns to accommodate itself to holiday hours.

It seems to me that this case may fairly be likened to that of the sensitive plant in constant illumination. There is the same continuance of the periodic movement on the first removal of a stimulus, and the same gradual loss of periodicity consequent on the *continued* absence of the stimulus.

From this kind of habitual action there is but a small step to those actions in which we say that memory comes into play. Dr. Carpenter[3] relates the case of a boy who, in consequence of an injury to his brain, never acquired the power of speech or of recognising in any way the minds of other people. In spite of this mental incapacity he had an extraordinary sense of order or regularity. Thus although he disliked personal interference, his hair having been one day cut at ten minutes past eleven, the next day and every following day he presented himself at ten minutes past eleven, as if by fate, and brought comb, towel, and scissors, and it was necessary to cut a snip of hair before he would be satisfied. Yet he had no knowledge whatever of clocks or watches, and was no less minutely punctual when placed beyond the reach of these aids.

It is hard to say whether this boy actually remembered at ten minutes past eleven that now was the time to have his hair cut, or whether it was an unconscious impulse that made him do so. But whether we call it habit or memory, there is the same knowledge of the lapse of time, the internal chronometry, as Dr. Carpenter calls it, which exists in the sensitive plant, and the same tendency to perform an action because it has been done previously. There is, in fact, hardly any distinction between habit and memory; if a man neglects to wind up his watch at night, he says that he forgot it, and this implies that memory normally impels him to wind it; but how little memory has to do with the process is proved by the fact that we have often to examine our watches again to see that they are wound up. It is the old problem of conscious and unconscious action. If a friend, in order to test our powers of self-control,[4] moves his hand rapidly near the face, we cannot help winking, though we know he will not hurt us; and when we are breaking through a hedge or thicket, we close our eyes voluntarily to keep twigs out. Here are two actions performed with the same object by the same muscles under command of the same nerves, yet one is said to be directed by the will and the other by instinct, and a great distinction is drawn between them. It seems to me that the presence of what Mr. Lewes calls "thought consciousness" is not the crucial point, and that if it is allowed that the sensitive plant is subject to habit (and this cannot be denied), it must, in fact, possess the germ of what, as it occurs in man, forms the groundwork of all mental physiology.

I am far from wishing to make a paradoxical or exaggerated statement of this resemblance between the periodic movements of plants and memory of the human mind. But the groundwork of both phenomena seems to be the repetition of a series of acts, or the recalling of a series of impressions, in a certain order at a certain time, because they have been repeated in that order and at that time on many previous occasions.

---

[1] Leaving out of the question the repose during diastole.

[2] In Mimosa at least.

[3] Schübler, quoted by Pfeffer ("Die periodische Bewegungen der Blattorgane," 1875, p. 36).

[1] This curious phenomenon was first observed by Millardet, who describes it as of rare occurrence. (Millardet, *loc. cit.*, p. 29.)

[2] Quoted by Pfeffer ("Periodische Bewegungen," p. 31).

[3] "Mental Physiology," p. 349.

[4] See "Physiology of Common Life," vol. ii. p. 200.

I will mention one more fact in connection with the movements of Mimosa, in which the formation of habit is illustrated. Every one knows that a noise regularly repeated ceases to disturb us; that one becomes habituated to it, and almost ceases to hear it. A boy fast asleep inside an iron boiler while riveting is going on, is an example of this power of habituation. The same thing occurs with the Sensitive Plant. A single violent shake causes the main stalk to drop, and the leaflets to shut up; in a minute or two the leaf recovers, and will again react on being disturbed. In order to test the power of habituation, I fastened one end of a thread to the leaf of a sensitive plant, and the other to the pendulum of a metronome, and placed the plant just at such a distance from the instrument that it received a pull at every beat. The first shock caused the leaf to shut up, but after a few repetitions it became accustomed to it, and I had the curious sight of a highly-sensitive plant unaffected by a series of blows. In nature this power no doubt enables the plant to withstand the constant shaking of the wind.

In spite of the amount of time which has been spent on the study of sensitive and sleeping plants, no satisfactory explanation of the use which the movements are to the plant has ever been given. In the case of the carnivorous plants, we saw that the movements of plants may be offensive, and like the movements of animals in securing its prey. In the case of certain flowers which we will now consider, the movements are *defensive*, like the closing of a sea anemone. I shall describe these movements with a view to showing the existence of periodicity or habit, and some other general resemblances to animal physiology.

The crocus is perhaps the best example of a flower which opens and shuts in accordance with changes of external circumstances. The crocus is especially sensitive to changes of temperature. If a light index is fastened into one of the petals or divisions of the flower, very small movements are made visible, and in this way it has been shown that the crocus actually appreciates a difference of temperature of one degree Fahrenheit.[1] I have seen a crocus distinctly open when a hot coal was brought near it. The use of this power of movement is connected with the fertilisation of the flower. In the warm sunshine the flower opens wide, and the bees are soon hard at work, and carry pollen from one flower to another. If, now, a cloud hides the sun, the temperature falls, and the crocus begins to close, and by the time the sky has become overcast and the first drops of rain fall, the precious pollen is housed safe beneath the roof of petals. The crocus is warned of the coming danger by the shadow of the cloud just as the fly is warned by the shadow of the approaching hand. The crocus is sensitive to changes of light and darkness as well as to changes of temperature, and the sum of these influences alternately acting by night and day produce a periodic opening and shutting which resembles the periodic movement or sleep of the Sensitive Plant. Corresponding to the regular repetition of the stimulus of light and heat, an internal periodicity has arisen in the flower which shows itself in a curious manner. This phenomenon is best shown by certain flowers which are not so sensitive to temporary changes, but which open and close regularly by day and night. Raising the temperature in the evening does not produce nearly the same amount of divergence of the petals as a similar rise in the morning. With the white waterlily, *Oxalis rosea*, and some other flowers, the same thing is well seen.[2] If the flowers have been allowed to close at the natural hour in the evening it is hardly possible to perceive the least opening of the petals even when the temperature is raised from 50° to 82°. On the other hand a considerable lowering of temperature does not produce so much effect in the morning as it does towards evening. In all biological problems it is necessary to consider the internal condition of the organism quite as much as the other element, viz., the external condition. It is a familiar fact that similar external causes do not produce like results. A man may fall ill after exposure to wet and cold at different times of his life and the kind of illness may be very different. Once it may be rheumatic fever, another time pleurisy, or some other malady, so that in the case of the flowers' which, under a given change of temperature, behave differently at different times of day, we see the variability in the internal condition or receptive state of the organism exemplified, the most interesting fact being that the receptiveness varies not capriciously but with periodicity.

The same phenomenon may also be seen when the cycle is a yearly and not a daily one. A German physiologist has lately made a long and patient research on the yearly periodicity in the growth of buds.[1] The method consisted in ascertaining the weight of 100 cherry buds gathered at frequently repeated intervals throughout the year. In order to discover whether the growth of buds would be equally increased in rapidity at all times by a given increase of temperature, branches were cut and kept in a greenhouse at a temperature of 60 to 70 at various times of the year. This experiment showed that branches thus treated in the beginning of December were hardly at all hurried on in growth, while the rise of temperature at once produced energetic growth in buds in the middle of January. If this fact is to be classed with the very similar effects of temperature on the daily periodic changes in flowers—and I can hardly doubt that it ought to be so classed —a difficulty arises. The buds being new growths, have never experienced a previous winter or spring, so that the periodicity cannot originate in their tissues; it must, therefore, depend on some property common to all the branches, some periodicity common to the nutrition of the tree. Askenasy describes the case as the occurrence of some chemical change which goes on in the buds, rendering them sensitive to rise of temperature at a certain period. The case bears a resemblance to the hybernation of animals. Thus, Berthold[2] says that when the dormouse, *Myoxus avellanarius* first goes to sleep in the autumn, it can be partly awakened, and then sent into deep sleep by alternations of temperature, answering, like the crocus, to alternations of heat and cold; but when the winter sleep has fairly set in, no effect could be produced by raising the temperature,—just as the oxalis and water lily when once shut for the night could not be made to open.

I have no doubt that many closer analogies will some day be shown to exist between the behaviour of plants and animals, as regards nerve-physiology. The after effect of stimuli seems to be represented in the movements of plants. If a stimulus is suddenly applied and then removed, the nerves acted on do not cease to be disturbed the instant the stimulus ceases. The molecular change, whatever it is, which goes on in the nerve, cannot leave off directly the stimulus ceases. The molecular action goes on like the vibration of a bell after it has been struck. When a wheel is turned round rapidly before our eyes the image of a new spoke strikes the retina before the image of the old one has died away, so that we cannot distinguish one from another. In the same way a burning stick whirled round looks like a circle of fire. This after effect of stimuli is represented in plants by heliotropism and geotropism. I have myself observed it in the latter. I took a young growing shoot and put it through a hole in a cork, so that it was firmly fixed into a bottle of water. I then put the bottle on its side in a vessel filled with wet sand, and fixed it firmly by piling wet sand over it. The shoot thus projected horizontally from the vessel of sand. It now began to straighten itself by geotropism, that is to say, the tip of the shoot began to curve upwards. I applied a delicate means of measuring this upward movement, and allowed it to continue for some time. I then turned the bottle round on its axis, so as to rest on what had been its upper surface, and the action of gravity being now reversed as far as the shoot went, the tip ought to have reversed its direction of growth, and curved upwards, but instead of this it went on curving towards the earth in consequence of the after-effect of the old stimulus. And it was more than an hour before it could reverse its movement, and again grow upwards.

With this case I conclude my comparison of plants and animals. Some of the points of resemblance which I have attempted to point out are purely analogical. Nevertheless, I have tried to show that a true relationship exists between the physiology of the two kingdoms. Until a man begins to work at plants, he is apt to grant to them the word "alive" in rather a meagre sense. But the more he works, the more vivid does the sense of their vitality become. The plant physiologist has much to learn from the worker who confines himself to animals. Possibly, however, the process may be partly reversed—it may be that from the study of plant-physiology we can learn something about the machinery of our own lives.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Vice-Chancellor has published, for the information of the Senate, a statement received from the University Commission. There appears to the Commissioners to be sufficient evidence of needs which will ultimately require a contribution equivalent to, at least, ten per cent. of the net income of the Colleges. The Commissioners think it will be sufficient to specify in general among the purposes for which provision should be made :—

"1. Additional buildings for museums, laboratories, libraries, lecture-rooms, and other rooms for University business.

"2. The maintenance and furnishing of such buildings, including the provision of instruments and apparatus, together with the employment of curators, assistants, skilled workmen, and servants.

"3. Additional teaching power by the institution of new permanent or temporary professorships, and the employment of lecturers and readers, including the increase of the stipends of some of the existing professorships and the provision of retiring pensions.

"4. Grants for special work in the way of research, or for investigations conducted in any branch of learning or science connected with the sudies of the University.

"The sources from which funds for the purposes described should be obtained appear to be clearly pointed out by the Act itself, when it empowers the Commisioners to enable or require the several Colleges, or any of them, to make contributions out of their revenues for University purposes, regard being first had to the wants of the several colleges in themselves for educational and other collegiate purposes.

"The principles on which payments from the Colleges should be contributed are, in the opinion of the Commissioners, as follows :—

"That such contributions should be made by the several colleges as nearly as possible on a uniform scale throughout, whether by annual payments to the proposed common University fund, or by a capital sum to be provided by the college out of money belonging to it in lieu of such annual payments ; or by annexing any college emolument to any office in the University, with specified conditions of residence, study, and duty ; or by assigning a portion of the revenue or property of the college as a contribution to the common fund, or otherwise, for encouragement of instruction in the University in any art, or science, or other branch of learning, or for the maintenance and benefit of persons of known ability and learning, studying, or making researches in any art or science, or other branch of learning in the University ; or by providing out of the revenue of the college for payments to be made, under the supervision of the University, for work done or investigations conducted in any branch of learning or inquiry connected with the studies of the University within the University.

"The Commissioners think it probable that over and above the contributions to be required from the college on a uniform basis, some colleges may be willing, following in this respect the example of Trinity College, and in consideration of prospective additions to their revenues, or for other reasons, to contribute to the wants of the University by founding professorships or otherwise."

OXFORD.—The vacant Burdett Coutts Scholarship has been awarded to Mr. Edward B. Poulton, B.A., Scholar of Jesus College. The examiners have also announced that Mr. Francis H. Butler, B.A., Worcester College, distinguished himself in the examination and is worthy of honourable mention.

GLASGOW.—At a private meeting of the members of the University Council to consider who should fill the vacancy in the Chancellorship caused by the death of Sir William Stirling-Maxwell, fifty members voted for the Duke of Buccleugh, and thirty-one for Sir Joseph Hooker. A committee was appointed to endeavour to concentrate the vote upon the duke.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 7.—"Experimental Researches on the Temperature of the Head," by J. S. Lombard, M.D., formerly Assistant-Professor of Physiology in Harvard University, U.S. Communicated by H. Charlton Bastian, M.D., F.R.S., Professor of Pathological Anatomy in University College, London.

"Addition to Memoir on the Transformation of Elliptic Functions," by A. Cayley, F.R.S., Sadlerian Professor of Pure Mathematics in the University of Cambridge.

March 14.—"On the Function of the Sides of the Vessel in maintaining the State of Supersaturation," by Charles Tomlinson, F.R.S.

Anthropological Institute, February 26.—Mr. John Evans, D.C.L., F.R.S., president, in the chair.—The following new Members were announced :—Mr. W. Cohen and Mr. Gabriel.—A weapon from New Zealand was exhibited by Mr. Hyde Clarke.—Mr. J. Sanderson exhibited some stone implements and fragments of pottery from Natal, and read a paper on the subject of the present native inhabitants and their legends. The President remarked that the great bulk of the implements exhibited were extremely rude ; and in respect to the pottery, observed that it presented remarkable similarity in pattern to pottery found in this country, a statement confirmed by the Rev. Canon Greenwell, who remarked that the pottery was hard and well-baked, and probably made for use in the household.—Mr. W. St. Chad Boscawen read a paper on the primitive culture of Babylonia, in which he referred to the rudely pictorial character of early Babylonian writing, and to its gradual development into a syllabic character, as shown in the syllabaries of Assur-banipal, which he illustrated by reference to the growth of pronominal ideas and the change of the archaic forms through hieratic into a court, or script hand. Treating the earlier forms as pictorial, he suggested that they gave evidence that the original form of dwelling was a cave, which then gave place to a construction of wattle and daub, and that to a structure supported by wooden beams on columns, and having doors and windows. To these were probably attached gardens about the entrance. The honour in which women were held by their children is indicated by the ideograph for mother, which signifies "home-divinity." Mr. Boscawen then stated, as his opinion, that the early Babylonians used the fire-stick to kindle their fires. The ideograph for "prison" is "dark-hole." In these early cities there were policemen who patrolled day and night. A vast number of other curious illustrations of the manners of ancient Babylon were deduced by Mr. Boscawen from the ideographs and syllabaries, and his lecture was listened to with great interest.

Physical Society, March 2.—Prof. W. G. Adams, president, in the chair.—The following candidates were elected Members of the Society :—Mr. J. P. Kirkman and Dr. W. J. Russell, F.R.S.—Mr. Sedley Taylor exhibited the colours produced in thin films by sonorous vibrations. A piece of thin brass perforated with a triangular, circular, or rectangular aperture, and bearing a thin film of soap solution, was placed horizontally on one end of an L-shaped tube ; the beam of the electric lamp, after reflection from it, was received on a screen. It was shown that when a sound is emitted in the neighbourhood of the open end of the tube, the film takes up a regular form which is indicated by the different colours of the reflected light, and each note has its own particular colour figure ; and further, with different instruments we have different figures. Thus when a square film was employed a kind of coloured grating was the result, which was modified by changing the note, and with a circular film concentric rings traversed by two bars at right-angles were observed.—Mr. W. H. Preece exhibited and described the phonograph. After referring to the manner in which the preceding communication bore on the subject of the telephone, he went on to explain the construction of the two instruments exhibited, which have been made in accordance with the published accounts of the apparatus and details received from the inventor, Mr. T. A. Edison, by Mr. Pidgeon and Mr. Stroh respectively. In the first of these the receiving and emitting discs are distinct, the former being of ferrotype iron, and the latter of paper, whereas, in the second form of apparatus, both these functions are performed by one and the same disc of iron. They also differ in that in Mr. Pidgeon's apparatus the drum receives its motion by hand, and in that of Mr. Stroh a descending weight is caused to communicate motion by a suitable train of wheels, which motion can be controlled and regulated by an adjustable pair of vanes. In both cases the drum is of brass traced over by a spiral groove, and the whole is mounted on a screw of the same pitch. The manner of using the phonograph is extremely simple. The drum having been covered with tinfoil, a uniform movement of rotation is given to it, and a fine metal point, firmly fixed to the centre of the receiving plate, is brought in contact with it, care being taken to place the point accurately over the groove. If now this plate be sung or spoken to, the tinfoil will be indented in accordance with the vibrations communicated to the plate. The emitting plate having been provided with a resonator, its point is now brought into the position initially occupied by the point of the receiving plate, and on rotating the drum, with the same velocity, fairly identical sounds are given out. It will be seen that Mr. Stroh's apparatus has an advantage over that of Mr. Pidgeon, in that it secures a constant rate of rotation; but on the other hand, the sounds emitted by the paper disc appeared to be more distinct than those from the iron. A number of experiments were performed with the instruments. The sounds were reproduced at times with remarkable distinctness, and when Mr. Spagnoletti and Mr. Sedley Taylor sang "God Save the Queen," as a duet, through a double mouthpiece, the two voices could be clearly distinguished on its being reproduced. It was shown that even when an indented sheet of tinfoil has been employed to emit sounds, it retains its form with such perfectness that the sounds can be reproduced by means of it a second, and even a third time, with nearly equal distinctness. Prof. Graham Bell pointed out that the articulation of the instruments was very similar to what he had observed in the earlier forms of telephone, and he had no doubt, judging from his own experience of that instrument, that the phonograph will ere long be so adjusted as to articulate much more perfectly. He anticipated that the *quality* of the sound would be found to vary as the rate of rotation was altered, as well as the pitch, and this proved on experiment to be the case.

Royal Microscopical Society, March 6.—Mr. H. J. Slack, president, in the chair.—Mr. Chas. Stewart described a new species of coral said to have been obtained from an island in the vicinity of Tahiti, and which was referred to the genus *Stylaster*. The characteristics of the genus and the distinctive features of the new species were explained and illustrated by black board drawings, and specimens of the coral were exhibited under the microscope.—A paper on a new operculated infusorian from New Zealand, by Mr. Hutton, of Otago, was read by the president.—A paper by Mr. Adolf Schulze on a new and simple method of resolving the finest balsam-mounted diatom tests, was read by the secretary, and described the success which had attended the examination of this class of objects by means of the reflex-illuminator, and the immersion paraboloid, moistened with castor oil in place of water. The lines on *Amphipleura pellucida* were shown in this manner by Dr. Dickson, in illustration of the paper.—Lissajous curves drawn microscopically upon glass by Mr. West, were exhibited by Mr. Curties.

Institution of Civil Engineers, February 26.—Mr. W. H. Barlow, vice-president, in the chair.—The paper read was on liquid fuels, by Mr. H. Aydon.

Victoria (Philosophical) Institute, March 4.—A paper was read by the Rev. Dr. Rule, in reference to ancient Oriental monuments.

CAMBRIDGE

Philosophical Society, February 11.—Mr. J. W. L. Glaisher made a communication on the mode of formation of the factor table for the fourth million, now in course of construction.

PARIS

Academy of Sciences, March 11.—M. Fizeau in the chair.—The following papers were read:—On the phenomena connected with vision of coloured objects in motion, by M. Chevreul. He is able to show on a circle, one-half of which is black, the other half coloured, the complement of this colour, and prove that it is due to the arrangement of the two surfaces with regard to circular motion.—On some applications of elliptical functions (continued), by M. Hermite.—On the relative affinities and reciprocal displacements of oxygen and halogen elements combined with metallic substances, by M. Berthelot. The comparative reactions of the halogens and oxygen on various metals, and specially the reciprocal displacement between iodine and oxygen, depend neither on type nor on atomic or other formulæ of the combinations, but on the quantities of heat liberated by direct combination of the metals with each of the antagonistic elements taken in equivalent weights.—Influence of M. Pasteur's discoveries on the progress of surgery, by M. Sedillot. He shows the relation (to those discoveries) of Lister's treatment of wounds and its results; also Guerin's (with wadding, &c.). M. D'Abbadie stated that on the shores of the Red Sea the natives have a maxim that a wound, to be healed, should remain in contact with air; and he found this was the case. He thinks the air may there be free from microbes.—The vibrations of matter and the waves of the ether in chemical combinations, by M. Favé.—On Mr. Edison's phonograph, by M. du Moncel.—On the industrial applications of electricity, by M. Du Moncel. This is a short summary of vol. v. of his "Exposé des Applications de l'Électricité" (third edition).—M. Cialdi was elected correspondent for the section of Geography and Navigation, in room of the Emperor of Brazil, elected Foreign Associate.—On elliptic polarisation by reflection at the surface of transparent bodies, by M. Cornu.—Note on the vibrations of liquids, by M. Barthélemy. A claim of priority.—Discovery of a small planet at the Observatory of Pola, by M. Palisa.—Observations of small planets, by M. Palisa.—On the fundamental points of the system of surfaces defined by an equation with partial derivatives of the first algebraic order, linear with regard to these derivatives, by M. Fouret.—On a class of transcendant functions, by M. Picard.—On the variations of terrestrial magnetism, by M. Quet. He examines, with the aid of calculation, the theory which attributes to the sun a direct action on the magnetic and electric fluids of the earth.—On the precise orientation of the principal section of Nicols, in apparatus of polarisation, by M. Laurent. For this purpose he places between polariser and analyser a diaphragm, one-half of which only is covered with a thin plate of quartz parallel to the axis, having the thickness of half a wave. When the Nicol, *e.g.*, has to be placed at a determinate angle to certain reticular wires, the border of the plate is brought into the position, then the Nicols are placed accordingly.—Study of chloride of sulphur, by M. Isambert. There is only one chloride of sulphur in which the chloride is dissolved in considerable proportion at a low temperature.—On the substitution of sulphur for oxygen in the fatty series, by M. Dupré.—On the catechines (third note). Catechines of gambirs, by M. Gautier.—Action of fluoride of boron on organic matters (benzylic aldehyde, ethylene), by M. Landolph.—On a new pyrogenous derivative of tartaric acid, dipyrotartaric acetone, by M. Bourgoin.—On the acid of gastric juice, by M. Richet. The hydrochloric acid of gastric juice is in combination with tyrosine, leucine, and perhaps other similar substances.—Experimental researches on the inequality of the corresponding regions of the brain, by M. Le Bon. He examined 287 skulls in the Museum of Anthropology, and found 125 with predominance of the right side over the left, 111 with predominance of the left side, and 51 in which the bones were unequal but compensated each other, making the right side nearly equal to the left.—Classification of Stellerides, by M. Viguier.—On Garnierite, by M. Garnier.—Artificial production of brochantite, by M. Meunier. This was done by keeping fragments of galena about eleven months in a moderately concentrated solution of sulphate of copper.—The Silurian Tigillites, by M. Crié. He attributes those in the west of France to ancient plants, of calamitoid aspect, that lived in shallow water.—On the *rôle* of the retina in vision of near or distant objects, by M. Fano.

SCIENTIFIC WORTHIES

XII.—WILLIAM HARVEY,[1] BORN APRIL 1, 1578, DIED JUNE 3, 1658

WILLIAM HARVEY was born three hundred years ago, on the first of April, 1578, at Folkestone, in Kent. He was the eldest son of his father; who seems to have been a substantial farmer, wealthy enough to send his eldest son to the university and to embark his five other male children in the mercantile pursuits in which they all acquired riches. At sixteen, Harvey was sent to Caius College, Cambridge, and graduated B.A. at nineteen. But, desiring to become a physician, Harvey wisely determined to proceed with his medical studies at one of the great continental seats of learning; and, by good hap, chose the University of Padua, which had been famous for a long succession of admirable anatomists, among them Vesalius and Fabricius of Aquapendente, who was the incumbent of the anatomical chair in Harvey's time.

After five years' study at Padua, Harvey took his doctor's degree in 1602, returned to England, and obtained the doctorate of his own university. In 1604, he married, began practice in London, and five years afterwards became physician to St. Bartholomew's Hospital. In 1615, Harvey was elected "Professor of Anatomy and Surgery" by the College of Physicians, and his first course of lectures was delivered in 1616. It is possible that he expounded his ideas respecting the circulation of the blood on this occasion; but, in this case, it is not obvious why he himself, in the dedication of the "Exercitatio Anatomica de Motu Cordis et Sanguinis," published in 1628, should not have said so. On the contrary he writes:—

> "Meam *de motu et usu cordis et circuitu sanguinis* sententiam E.D.D. antea sæpius in prælectionibus meis anatomicis aperui novam; sed jam per novem et amplius annos multis ocularibus demonstrationibus in conspectu vestro confirmatam, rationibus et argumentis illustratam, et ab objectionibus doctissimorum et peritissimorum anatomicorum liberatam, toties ab omnibus desideratam, à quibusdam efflagitatam, in lucem et conspectum omnium hoc libello produximus."

Why "jam per novem et amplius annos," if he had really taught the circulation "per duodecim annos?" Harvey is so careful a writer that I cannot doubt he had a meaning in the use of the particular words he has adopted, and that he did not wish to lay claim to having enunciated his complete views before 1618 or 1619.

However this may be, the famous treatise itself was not given to the public until 1628, and its appearance conferred upon its author a fame which rapidly extended over the civilised world. James the First died in 1625, and it is, on the whole, pleasant to reflect that Harvey owed nothing to that foul pedant. But his son was a man of a different stamp, and whatever the verdict on his political deeds may be, shines as one of the few English sovereigns who have shown an enlightened sympathy with letters, with science, and with art. Harvey became Charles the First's physician about 1632, and the monarch repaid the real respect and affection with which his eminent subject evidently regarded him, in the only way for which Harvey was likely to care; namely, by doing his best to aid him in his investigations, and taking a cordial and intelligent interest in them.

Between 1630 and 1632, Harvey travelled on the Continent with the young Duke of Lennox; and, in 1636, he was physician to the Earl of Arundel's embassy to the Emperor. During this visit, he is said to have tried to convince Caspar Hofmann, of Nuremberg, of the circulation of the blood, experimentally, but in vain. When the troubles between the King and the Parliament broke out, Harvey accompanied his master in his campaigns He was at the battle of Edgehill, in charge of the Prince of Wales and the Duke of York; and he told Aubrey that "he withdrew with them under a hedge, and tooke out of his pockett a booke and read. But he had not read very long before a bullet of a great gun grazed on the ground neare him, which made him remove his station."

By the King's order, Harvey was elected Warden of Merton College, Oxford, in 1645; and to the same efficient cause, or to the fact that he was the King's physician, we must probably look for the conference of an honorary degree by the University of that day on a mere scientific discoverer. But, after the surrender of Oxford in the following year, Harvey retired from public life altogether, and spent the remainder of his days at the homes of one or other of his brothers, in the neighbourhood of London.

In 1649 Harvey, published his two letters to Riolan, which form a supplement to the "Exercitatio Anatomica;" and, in 1651, when he had reached the ripe age of seventy-three, the "Exercitationes de Generatione" appeared. "The rest is silence," save a few letters. In the last of them we have, dated April 24, 1657, he writes to Vlackveld:—

> "Frustra autem calcar mihi addis, ut in ætate hac, non solum matura, sed etiam fessa, ad aliquid noviter moliendum me accingam. Videor enim jam mihi, meo jure, rudem deposcere."

No man had a better right to claim an honourable discharge from duty. Six weeks later the wished-for release arrived, and on June 3,

Spectatum satis et donatum jam rude,

Harvey died in the eightieth year of his age, full of honours as of years, more than sufficiently wealthy, and able long before his death, to say that the great truth he had discovered and taught was accepted by all whose opinion was worth having.[1]

The only works which Harvey published famous treatise on the Circulation (1628), with letters to Riolan (1649), and the "Exercises on tion (1651)." But he was a most diligent obser writer, and he incidentally refers to a "Disquisition the Causes and the Organs of Respiration," to "Medi Observations," to a treatise "On the Generation of Insects," and to many observations on Comparative

---

[1] The portrait of Harvey will be presented to our readers in one of the May numbers of NATURE. Though every facility has been afforded by the College of Physicians, there has been unavoidable delay in its preparation. ED.

VOL. XVII.—No. 439

Anatomy, the whole of which appear to have been destroyed when his house was plundered with the connivance, if not by order, of the Parliament, during his absence from London with the King.

Of the "Exercitatio de Motu Cordis et Sanguinis," I have treated so fully elsewhere[1] on a recent occasion, that I will again not touch upon the subject except so far as to repeat that, in my judgment, Harvey is entitled, beyond dispute, to be regarded as the sole discoverer of the circulation of the blood, and of the method of its propulsion by the heart.

The story of the extraction of the manuscript of the "Exercitationes de Generatione" from Harvey is well told by Ent, who undertook the charge of seeing the work through the press; a task of no small magnitude if we consider the superlative badness of the extant specimens of Harvey's handwriting.

The preface contains a singularly interesting disquisition on scientific method; and, among other observations the following, which is, perhaps, the weightiest in small compass ever laid before the student of physical science.

"For those who read the words of authors, and to whom impressions of their own senses do not represent the things signified by those words, conceive, not true ideas, but falsæ eidola and inane phantoms; whence they fill their minds with shadows and chimæras, and their whole theory (which they think to be science) represents but a waking dream or a sick man's delirium."

As in the case of the circulation of the blood, the scientific opinions of the day respecting the conditions of generation and the embryogenic process had descended from the Greeks. No one doubted that a large proportion of the lower forms of life owed their origin to equivocal or spontaneous generation, or, as it is now termed, abiogenesis; and, with respect to sexual generation, it was believed that the embryo originated at the time of sexual union, by the combination of two substances poured out *ad hoc*, the one being derived from the female, the other from the male parent. In this opinion both Aristotle and the Medici, following Galen, agreed; but they differed in the view which they took as to the nature and function of the two sexual elements. According to Aristotle, the female supplied merely the material of the embryo, by the excretion of a substance which he regarded as the purest part of the catamenial blood; this was coagulated, and endowed with the faculty of developing into an organism, by the spermatic fluid, of the male. The Medici, on the other hand, considered that the female produced a true spermatic fluid, analogous to that of the male, and having an equal formative energy; and indeed, that the sex of the embryo was determined by the predominance of the one or the other spermatic fluid.

As regards the embryogenic process itself, the Greeks had studied the development of the chick, and had learned somewhat respecting the fœtal state of viviparous animals; while, since the revival of learning, several important embryological investigations had been undertaken. Of these the most notable were those of Aldrovandus, of Coiter, of Harvey's master, Fabricius of Aquapendente, of Vesling, and of Parisanus, on the development of the chick. Fabricius' treatise, "De Ovo et Pullo," was accompanied by figures of the stages of development, which, for the time, must be termed very good; and it served Harvey as a sort of text-book, to which he constantly refers.

The "Exercitationes" show no advance on the knowledge of the ancients respecting the conditions of generation. Innumerable passages show that Harvey believed, as firmly as his predecessors and contemporaries did, in equivocal generation.[1] The persistent ascription to Harvey of the contrary opinion is simply astounding, and can only be explained on the supposition that those who quote what they are pleased to call "Harvey's aphorism," "Omne Vivum ex Ovo," against the holders of the doctrine of spontaneous generation, have never read the works of their authority.

I cannot discover the exact phrase "omne vivum ex ovo" anywhere in Harvey's works, though it is true that the sense of the words is expressed by him over and over again. But the context shows his meaning to be, not the assertion of the doctrine of biogenesis; but simply a declaration that, in whatever way a living being is generated, the nature which it at first possesses is that of an egg. And what Harvey wants to impress, by the frequent iteration of his opinion on this subject, is the difference between his view, that a germ is something which comes into existence more or less as a unit and has an individuality of its own, and that of his predecessors, who held that it is formed by the coalescence of separate entities. Nevertheless, there is an indication that Harvey was on the right track in respect of the question of spontaneous generation; and that, if his papers on the generation of insects had not been destroyed, he might have anticipated Redi; for the forty-first exercise contains the following remarkable passage:—

"But on these matters generally we shall have much to say, when we shall show that many animals, especially insects, take their origin and are generated from elements and seeds so small as to escape observation (like atoms floating in the air), which are scattered and dispersed hither and thither by the winds; yet these animals are supposed to arise spontaneously, or from putrefaction, because their germs are nowhere to be found."

It was exactly this thesis that Redi adopted and proved to demonstration, seventeen years afterwards, and therefore long before Harvey's death; and it is by following up the same line of argument that modern investigators have deprived abiogenesis of its last supposed experimental evidence. In whatever way, however, the germ of a plant or of an animal is produced it is the equivalent of an egg, and what Harvey means by an egg is clearly shown, in the following as in many other passages:—

"In the generation of all living things (as we have said) this is established, that they arise from some primordium (primordio aliquo) which contains not only the matter but the power of generation; and is, therefore, that out of which and from which the thing generated takes its origin. Such a primordium in animals (whether they proceed from parents, or arise spontaneously or out of putrefaction) is a humour contained in a membrane of some kind, or shell; in fact, a homogeneous body (corpus nempe similare) possessing life, either actually or potentially. This primordium, if it is generated within an animal and remains there, until a like animal (univocum) is produced, is vulgarly called a *conception*; if, however, it is thrust out by parturition, or if it has originated elsewhere by chance, it is termed an *ovum* or *vermis*. I think, however, that, in either case, that from which an animal arises should be called primordium; just as plants produce their young from seeds; and that all these primordia are of one kind, namely, living things.

---

[1] "William Harvey," *Fortnightly Review*, February 1, 1878.

[1] I pointed this out twenty years ago in my "Lectures on General Natural History," published in the *Medical Times and Gazette*. Take one passage out of fifty that might be cited: "Atque etiam terra suâ sponte plurima generat sine semine" (Exercit. xxix.). M. Pouchet might have taken this sentence for a motto.

"I find a primordium of this sort in the uterus of all viviparous animals, before any fœtus can be discerned. In fact, there is a clear, viscid, white [colourless] fluid, like the white of an egg, inclosed in a membrane, which I term the egg of these animals; and, in red-deer and fallow deer, in sheep and other cloven-footed animals, it fills the whole uterus and both its cornua."[1]

It will be observed that, in the foregoing passage, Harvey insists upon one main quality of the primordium, namely, that it is a *corpus similare*; or, in other words, that it is relatively homogeneous; and, in the seventy-second exercise, "De humido primogenio," he insists strongly on what he believes to be the fact that the embryo takes its rise in a certain "humidum radicale et primigenium," "simplicissimum, purissimum et sincerissimum corpus," in which all the parts of the embryo are present potentially, but not actually, and out of which they arise by a gradual process of differentiation.

"The first rudiment of the body is a mere homogeneous and soft jelly, not unlike a spermatic coagulum, which, becoming changed (in accordance with the law of generation) and at the same time split or divided into many parts, as by a divine command, as we have said (let bone arise here, muscle or nerve there, here viscera, there receptacles of excretion, &c.) out of the inorganic arises the organic, out of the similar the dissimilar; out of the one and the same nature, many things of diverse and of contrary natures; not, indeed, by any transposition or local motion (as when by the power of heat homogeneous things unite, or heterogeneous things are separated), but rather by the disaggregation of homogeneous things, than by the aggregation of heterogeneous things."[2]

In this passage, as in those in which he advocates *epigenesis*, Harvey shows a complete grasp of the great truth that development is a gradual process of change from relative homogeneity to heterogeneity, put into such clear light in our own time by Meckel and von Baer.

Again, when Harvey dwells upon the close resemblance of the early conditions of the higher animals, and accounts for harelip as a retention of an embryonic condition, we see him hovering on the brink of some of the most important embryological generalisations of a century and a half after his time.

After Harvey, embryological theory distinctly retrograded for a full century, until, in fact, a hundred and eight years had elapsed, and, in 1759, Caspar Friedrich Wolff published his "Theoria Generationis." In the interval, the great truths laid down by Harvey, that all germs are homogeneous relatively to the forms to which they give rise, and that all those of the higher animals, at any rate, pass by *epigenesis* into the perfect living thing—"Fabrica a parte aliqua tanquam ab origine incipit: ejusque ope reliqua membra adsciscuntur: atque hæc per *epigenesin* fieri dicimus: sensim nempe partem post partem: estque isthæc, præaltera, proprie dicta generatio" (Exercitatio xlv.); these verities, justified by all our present knowledge, were ignored, and the doctrine of the "pre-existence of germs" and of "evolution" took their place. And so strong was the hold of the latter, that even Wolff's conclusive investigations produced little effect, and the full acceptance of Harvey's generalisations dates from the last half-century.

But while Harvey's views respecting the general nature of the embryogenic process were as much in advance of his time as were his doctrines respecting the motion of the heart and the circulation of the blood, his demonstration of them is a failure, the phenomena being too subtle and recondite for the means of investigation which he possessed.

So far as the process of fecundation is concerned, he is further from the truth than were the Greeks; for he steadily denies that the male element enters into the substance of the egg, or even comes into physical contact with it; and he ascribes the efficacy of the male to a sort of contagion, by which the female organism is infected, and in consequence of which, the ova, which he justly declares to be formed like any other growth, acquire the property of developing into embryos.

Again, though Harvey's discovery, that the region of the cicatricula in the hen's egg is the seat of the changes which give rise to the embryo, was of primary importance, he has not the least notion of the real nature of the cicatricula or of its relations to the yolk. The "primigenial radical humour," which he supposes to be the first commencement of the embryo, is nothing but the amniotic fluid, which is really formed long after the rudimentary body of the chick has appeared. And Harvey's supposition that the blood is that which is first formed and that the substance of the body grows round the vessels "like a mucor or fungus," is an error, which is, of course, enormous, and may seem unpardonable to any one who has not tried to make out the early stages of the development of the egg with the naked eye, or even aided by a hand-glass. It was the discovery that the rudiment of the body of the chick exists in the egg, long before Harvey supposed, that was one of the chief causes of the adoption of the notion of the pre-existence of germs which led to the "evolution" and "*emboitement*" hypotheses. Buffon, in fact, went so far as to say that the chick "exists fully formed (*en entier*) in the middle of the cicatricula when the egg leaves the body of the fowl,"[1] thereby erring as far as Harvey did, but in the opposite direction.

After due deduction is made for these errors and shortcomings, however, the great merit of having been the first to grasp the true principle of interpretation of the process of development, must, I think, be accorded to Harvey; and if we consider the part which the study o development has played, and must henceforward continue to play in biology, the "Exercitationes de Generatione," though second to the "Exercitatio Anatomica," can hardly be said to have another rival in the contemporary literature of biological science.

---

[1] "De Uteri Membranis et Humoribus." Elsewhere (Exercitatio xxvi.) Harvey says:—

"Ovum itaque est corpus naturale, virtute animali præditum: principio nempe motûs, transmutationis, quietis, et conservationis. Est denique ejusmodi, ut, ablato omni impedimento, in formam animalis abiturum sit; nec magis naturaliter gravia omnia, remotis obstaculis, deorsum tendunt; aut levia sursum moventur: quàm semen et ovum in plantam aut animal, insita a naturâ propensione, feruntur. Atque semen (atque etiam ovum) ejusdem fructus et finis, cujus est principium atque efficiens."

Modern morphology, no less than physiology, has its root in the work of William Harvey. T. H. HUXLEY

ZÖLLNER'S SCIENTIFIC PAPERS

Wissenschaftliche Abhandlungen (Erster Band). Von F. Zöllner. (Leipzig: L. Staackmann, 1878.)

IF we take a somewhat different course in reviewing this work from that which we should naturally adopt with works professedly scientific, we hope at least to justify our conduct to the reader before we finish. For, alas, all is not scientific that professes to be science, and even celestial minds can harbour very curious feelings and express them with most unmistakeable vigour, while not always striking above the belt.

The key-note of this work, as well as of a great deal of the other somewhat voluminous writings of Prof. Zöllner, is struck by himself in a foot-note to p. 129, where he tells us that "the aim of all his scientific efforts has been to contribute, as far as the ability given him permits, to the realisation" of a certain "hopeful project":—viz., the explanation of *all* molecular actions by means of that Law of Electric Attraction (due to W. Weber) which "has already been so fruitful in coördinating under one principle all electric and magnetic phenomena."

Very good and laudable:—though we may permit ourselves to say, in passing, probably very unpromising. But it is quite impossible to say what hints a competent mathematician may not obtain while he is attempting to prosecute the applications of any theory—however remote its principles may be from those which the experimental facts themselves suggest to the physical investigator in his laboratory. Unfortunately even this concession is thrown away upon Prof. Zöllner:—for he not only does not claim to be considered as a mathematician, but has on a former occasion (in his work on *Comets*) expressly denounced those who attempt "by differentiating and integrating" to get at natural laws. He is, as Helmholtz long ago said, a *genuine* Metaphysician, and (as such) is a curiosity really worthy of study:—not of course merely because he is a Metaphysician, but because in this nineteenth century he attempts to bring his metaphysics into pure physical science.

To a man whose whole object in scientific life is the establishment of Weber's Law as the fundamental fact of the Kosmos, of course all works are an Abomination in which even an attempt is made to show that *action at a distance* can be (and therefore *ought* to be) dispensed with. Hence Clerk-Maxwell's Theory, which, even its opponents must allow, has succeeded at least as well as Weber's in connecting and explaining the phenomena of electricity, magnetism, and light, must be demolished at all hazards. But the reader of Maxwell's great work on *Electricity*, who has seen in its very *Preface* that the main object of that work was to carry out to their legitimate mathematical developments the physical ideas of Faraday, will scarcely be prepared to find that Prof. Zöllner accepts Faraday and denounces Maxwell!

This *tour de force* is worthy of so accomplished a metaphysician. It is absolutely refreshing in its coolness! According to Prof. Zöllner, both Clerk-Maxwell and Sir W. Thomson (to whose advice the former owns his indebtedness) quote Faraday correctly, and yet altogether misapprehend his meaning! In fact we are now told, though not in so many words, that Faraday, whom we had all looked on as an opponent of action at a distance, was really a firm believer in it, and a strenuous advocate of it! Not only Faraday, but even Newton himself:—in spite of the celebrated *Letters to Bentley*, in which all of us have hitherto read the inconceivability of distance-action to any mind which "has in philosophic matters a competent faculty of thinking"—even Newton himself, it seems, believed in action at a distance!

On this no farther comment is necessary than one I made some time ago, when Prof. Zöllner, to his own satisfaction at least, proved me to be ignorant alike of Latin and of the very *First Law of Motion*;—viz, that "Prof. Zöllner should not attempt to criticise . . . until he acquires sufficient knowledge of British technical terms . . . "

That a good deal of Prof Zöllner's censure is due to his imperfect apprehension of English, will, I think, be allowed by every candid reader. I say nothing of numerous misspellings—sometimes ludicrous, such as "*in his sobber* (*sic*) *senses*"—which occurs twice at least (pp. 142, 711), because there are quite as many misspellings in the German, and all are, therefore, probably due to the printer. But it is a wonderful piece of information for us benighted islanders to be told that our foremost scientific men, while quoting Newton accurately, entirely miss, or rather misrepresent, his meaning. So wonderful that I certainly shall not be believed, unless I refer definitely to some of the inculpatory passages:—

[The passage (pp. 141-152) is too long for translation, so I give a small part only; restricting myself to the *tone* in which British authors are spoken of, for the *substance* of the accusation, such as it is, has been already indicated.]

> "One's impaired power of discovering contradictions prevents his recognising them as such even when the effect of the contrast is heightened by juxtaposition. Hence we must ascribe the non-retractation of such by their authors not to moral weakness but to incapacity. Hence also the surprising *naiveté* with which such men (*i.e.*, Sir W. Thomson, Clerk-Maxwell, *et hoc genus omne*) hand over to their critic the weapons with which to exterminate them, &c., &c. He who thinks it superfluous to bother himself with the thoughts of his predecessors and contemporaries loses *ipso facto* all right to consideration for himself and his writings. Such an author will in after time be forgotten, just as he has forgotten his predecessors, and this in the name of Eternal Right. For, only in the continuity of the mental work of successive generations is there security for the progress of Humanity!"

The reader of this will perhaps think that he has seen enough of Prof. Zöllner and his work:—enough at least to enable him to form a pretty shrewd guess as to the scientific value of the whole. But I must be excused if I trouble him with a few additional remarks on another aspect of the book.

Some years ago Prof. Helmholtz kindly undertook to revise the German translation of *Thomson and Tait's Natural Philosophy*, and was in consequence somewhat wildly attacked by Prof. Zöllner in the *Preface* to his book on *Comets*. To that attack Prof. Helmholtz replied in a very admirable article, of which a translation has already appeared in NATURE (vol. xi. pp. 149, 211).

The great crime which according to Prof. Zöllner was committed, was a double one. Sir W. Thomson and I ventured to express an opinion (to which we still adhere) unfavourable to theories such as that of Weber:—and Prof. Helmholtz so far forgot his duty as a German as to be responsible for the reproduction of our work in his native tongue! As we now know that the promulgation and extension of Weber's Theory has been the object of Prof. Zöllner's life-work, perhaps it was not unnatural that he should complain of such conduct. But it is quite another thing when, after being completely demolished from the *scientific* point of view, he returns to the attack in another style—bringing against the various persons named charges of a totally different character—though all equally groundless.

A great many of these arise undoubtedly from imperfect acquaintance with the English language. Thus, to take a ludicrous one, Prof. Zöllner evidently imagines that "smoke-rings" *must* be formed with tobacco-smoke? And he fancies that it was in a smoking party that Sir W. Thomson hit upon his hypothesis of vortex atoms. For, after translating part of Thomson's own account of his theory, he says that a "skilled and powerful tobacco-smoker was necessary to the experimental verification of it."

Smokers, to whose charmed circle Prof. Zollner evidently does not belong, can alone judge how skilled and powerful they would have to become before they could produce from their own lips the vortex rings, *full of sal-ammoniac crystals* and somewhere about six or eight inches in diameter, which Sir W. Thomson describes in the paper referred to. But Prof. Zöllner comes back to this notion, as he does to others, with absolutely "damnable iteration." Here is an instance (p. 103) which we paraphrase as follows:—

> "The reader will note that 'Tobacco-smoke' and a 'creative act' are the inseparable companions of Thomson's Vortex-atoms:—although in the whole of Helmholtz's paper, on which Sir W. Thomson has erected the airy structure of his hypotheses, there is not a single passage in which such things are alluded to.
>
> "Since Sir W. Thomson and the mathematical supporters of his hypotheses continually employ tobacco-smoke for the explanation of their views, I also may be permitted to employ the same medium to make clear my notions. Were I to describe the feelings with which I crossed the threshhold of the Vortex-world of Thomson after leaving the clear and bright Thought-world of Newton, Kant, and Faraday, I could not succeed better than by comparing them to those of the Alpine traveller who leaves the enlivening freshness of the clear mountain air to enter the tobacco-laden atmosphere of a muggy beerhouse!"

We next have Thomson's (and Helmholtz's) speculations as to the origin of life on the earth:—once more overhauled and torn to shreds. Then the unfortunate "luminous corpuscle" of Thomson and Tait has again to perform its antics—but in a somewhat new phase. For it is now shown to be due to the same inaccuracy of thought (Denkfehler) as the "moss-grown fragments."

"Only the yet undeveloped understanding of a child can content itself with such hypotheses, as it does with the answer to the child's question, 'Where did the new-born little brother or sister come from?' The mother soothes the childish causation-excitement with the answer, 'The Stork brought it':—on the correct presumption that the child will not farther inquire whence or from whom the Stork received the infant."

So far as I can judge without an attentive perusal of the whole 732 pages of the work (*Erster Band*), such as, amusing though it is throughout, I cannot spare time to bestow, Prof. Zöllner seems to think that Clerk-Maxwell, Thomson, and myself *believe in the existence* of those imaginary beings (invented by Maxwell, and called *Demons* by Thomson) who were introduced for the purpose solely of showing the true basis on which the Second Law of Thermodynamics has to be received as a fact in physical science! Hence we are treated to a whole Chapter called "*Thomson's Dämonen und die Schatten Plato's*."[1]

But it was well that this Chapter should be written. For Prof. Zöllner has recorded in it a discovery *of the very first order*:—if it be correct. He has held the two ends of a cord (sealed together) in his hand, while trefoil knots, *genuine* IRREDUCIBLE TREFOIL KNOTS, of which he gives us a picture, were developed upon it! He shows us the reasoning by which he was led to predict the possibility of this very wonderful achievement—absolutely unique in character, so far as I know, throughout the whole range of science. Prof. Klein, of Munich, some time ago showed, as is well known, that knots cannot exist in space of four dimensions. Hence Prof. Zöllner was led to conclude that beings (not, of course, *Thomson's Dämonen* nor *die Schatten Plato's*, for these are unscientific, and therefore impossible) in space of four dimensions could put an irreducible knot on an earthly string of which the ends were fastened together! It is some time since the Astronomer-Royal for Ireland told me *his* jocular mode of arguing from Klein's discovery:—viz., that all the secrets of the spiritualistic "rope-trick" could be at once explained by supposing that *inside* the mysterious cabinet (in which the tambourines and the musical boxes fly about) space was of four dimensions—so that the well-corded performers were at once loosed from their bonds on entering it! But Prof. Zöllner (with the assistance of the spiritualists) has tied knots by means of beings who exist in four dimensional space!!! Those who tied can of course loose, so that there is now (thanks to Prof. Zöllner and the spirits) no such thing as an irreducible knot!

I need say nothing of the treatment which Prof. Zöllner bestows on other scientific men with whom he has the misfortune to disagree: such as the imaginary *execution-scene* (pp. 377 416) of a distinguished Physiologist! Plain men in this country, and in Germany also I doubt not, have uncomfortably plain terms for such outbursts. But such things are not for a scientific journal. I can hardly divest myself of the impression that Prof. Zöllner, in spite of his oft-expressed utter detestation of "Jokelets" of all kinds (Witze, Scherze, &c.) has been led by his feelings of "sittlicher Entrüstung" to attempt the perpetration of a gigantic joke upon his readers. For I have looked in vain through this large volume for anything that can well be called *Science;* with the one exception of some remarkable experiments due to Fresnel, to which it is well that attention has been called.

---

[1] This is not the place to continue discussions with Prof. Clausius, but the reader of Prof. Zöllner's book should be warned that, extensive as is his reading, it does not always seem to include the most cogent arguments which have been presented on one or other side in several controversies of which he undertakes to give an account.

In conclusion, though I cannot make pretensions to any minute acquaintance with the German language, I think I may venture to suggest to Prof. Zöllner, for his next edition, a title which shall at least more accurately describe the contents of his work than does his present one. I cannot allow that the title "Scientific Papers" is at all correctly descriptive. But I think that something like the following would suit his book well:—

Patriotische
METAPHYSIK DER PHYSIK,
für moderne deutsche Verhältnisse.

Mit speciellem Bezug auf die vierte Dimension und den Socialdemokratismus bearbeitet.

With this little hint, which I hope will be taken, as it is meant, in good part, I heartily wish him and his work farewell.
P. G. TAIT

A DICTIONARY OF MUSIC

A Dictionary of Music and Musicians. By eminent writers, English and Foreign. With Illustrations and Woodcuts. Edited by George Grove, D.C.L. (London: Macmillan and Co., 1878.)

NO better proof of the spreading interest in musical subjects which is now taking place in England could be found than the publication of this important work. Although similar "Lexicons," some of them extending to the portentous dimensions which German monographs are apt to assume, are not uncommon in that country, there have, as far as the writer knows, been hitherto none in our language which exactly occupy the position aimed at by this. Those which most nearly approach it, are either somewhat antiquated, or, like the excellent little work of Dr. Stainer, propose to themselves a far more restricted object. Nor indeed is the reason of the difference in this respect between the two countries difficult to assign. In Germany the whole population is more or less musical; every little town or village has abundance of practical musicians, mostly playing stringed instruments, among its inhabitants, who not only can take their part efficiently in a quartette, or in a local orchestra, but who are sufficiently informed in musical theory and literature to furnish an intelligent public which can support and encourage extensive undertakings of a scientific and historical character.

In England, on the other hand, unlike Germany, there has been, until quite lately, as little of representative musical culture as there has been of really national soldiering. We had been content to leave the defence of our country, no less than the executive realisation of great artistic master-pieces, to a separate and stipendiary class; while the bulk of the nation had merely "assisted," according to the French sense of the word, by listening and applauding. In both instances we, to a considerable degree, realised the dreams of Plato's Utopia; and though in the one case our *φύλακες*, the army, in spite of its small size and its professional leaders, for education and gallantry are probably unparalleled, it is, perhaps, to be feared that the artistic class, the *μουσικοὶ*, have somewhat suffered from isolation and lack of responsibility.

To this cause, and to unthinking prejudice, must be referred the tone of depreciation if not of contempt, which in the last century attached to the name "fiddler." It is conspicuous in the "Tweedledum and tweedledee" epigram of Handel's day, and frequently crops out in the Johnsonian, and even in later periods. The altered feeling of the present day cannot be better illustrated, than by the public estimation of Rubinstein or Joachim, or the genuine national grief at the early death of Titiens.

But the reform in the republic of sweet sounds must come, and is coming, *ab extra.* Audiences themselves must be fairly proficient in an art to esteem its higher developments and manifestations. The supply, according to the laws of political economy, must precede the demand; nor can true æstheticism of any kind fully prosper until the bulk of the population have been educated up to its intelligent and critical comprehension. For the moment it may be that in this particular branch the outsiders have distanced the regular executants. It would be a severe, but not altogether false statement to make, that in modern England—which has really become a musical nation—all classes are musical except the musicians. It is certain that our grandest celebrations, such as those of Handel and that at Leeds, are festivals where the latter are only secondary to the hearty and enthusiastic willingness of a voluntary but well-disciplined non-professional choir. Indeed it might, *à priori*, be anticipated that such would be the case, since the fondness for music, although it may be materially developed by circumstances and education, still remains very much of a gift; and this gift, which forms the strongest motive to exertion in acquiring it, is far more likely to exist in one who turns to the subject from love than in those who have simply adopted its study by chance, or as a means of earning a livelihood.

That such is to a certain extent the fact, receives ample illustration from the very first page of Mr. Grove's initial number, in which are recorded the names of the contributors to the work. Including the editor himself, who, though not a professional musician, has earned, under the familiar initial which he here again adopts, a full title to speak with knowledge and authority on musical subjects, a large proportion of the writers are not dependent on the art or practice of music for their social status. Among them will be found clergymen, a consul, a colonel, a doctor, an engineer, a Queen's counsel, a schoolmaster, and many others, whose devotion to the cause of music must be purely voluntary and a labour of love. As it cannot be doubted that all alike have given proofs of their competence to undertake the task entrusted to them, it is surely no forced conclusion to regard their co-operation as evidence of the depth to which educated English society is now penetrated by this subtle and once neglected branch of æsthetic culture. To the same class, moreover, the work appeals for support, a support which is more than justified by the laborious care, the painstaking and punctilious accuracy displayed by the editor in its compilation.

The present instalment of the work is the first of a series of quarterly parts, and only contains the letter A, with part of letter B. On turning over the pages the articles which attract the eye are one on ABBREVIATIONS in music and one on ARPEGGIO, by Mr. Franklin Taylor; an interesting account of the ACADÉMIE DE MUSIQUE, by Mr. John Hullah; an excellent little treatise on ACCENT in music, with abundant musical examples, by Mr. Ebenezer Prout; another on ACCENTS in plain song, by the Rev. Thomas Helmore; instructions as to ACCOMPANIMENT, by Mr. Hopkins, of the Temple, supplemented by another article on ADDITIONAL ACCOMPANIMENTS, by Mr. Prout; ÆOLIAN HARP is from the pen of Mr. Hipkins; ANTHEM is given by Dr. Monk, of York; ARRANGEMENT, by Mr. Hubert Parry; BAGPIPE, by the writer of this notice. In the biographical department, which is especially full, a long and exhaustive account of the BACH family, by Herr Maczewski of Kaiserslautern, stands foremost. There are also interesting notices of ADOLPHE ADAM and of AUBER, by Mr. Franz Hueffer; of many Italian composers, by Mr. Edward H. Pember, Q.C., of DR. ARNE, and of ATTWOOD, by Mr. Husk, Librarian of the Sacred Harmonic Society; of DR. ARNOLD, and a sympathetic biography of MICHAEL BALFE, by the late Dr. Rimbault. Sir Frederic Ouseley and the Editor contribute several smaller notices. The names of English musicians appear to have received especial attention.

There can be no hesitation in saying that the work just commenced promises to fill a gap in English bibliography, and that it furnishes excellent material for reference. Besides this, it presents the collateral advantage of offering a charming combination of amusement and instruction for desultory reading in the many *horæ subsecivæ* which occur even in the lives of the most busy.

W. H. STONE

OUR BOOK SHELF

Pioneering in South Brazil. Three Years of Forest and Prairie Life in the Province of Paraná. By Thomas P. Biggs-Wither. Two vols. With Map and Illustrations. (London: John Murray, 1878.)

MR. BIGGS-WITHER has written two volumes of genuine and varied interest and much instruction, as a result of his three years' work in a little-known region of South Brazil. He went out as one of an engineering party to open up a road between the Atlantic and Pacific, and he traversed much of the country on the banks of the rivers Ivahy and Tibagy, tributaries of the Paraná. Much of his time was spent in the forests of this region, virtually unexplored, and presenting a splendid field for any enterprising naturalist. Mr. Wither is an excellent observer, and his book abounds with information on the natives, the natural history, and physical geography of the region. He met with many adventures, and suffered much from heat and insects, but altogether he seems to have had a thoroughly enjoyable time of it. He writes throughout in an attractive and simple style, and his work must be regarded as an important contribution to a knowledge of the luxuriant region with which it deals.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Phonograph

WE shall be much obliged if you will allow us to draw the attention of your readers to a curious fact which the phonograph has allowed us to prove, and which we announced last Monday at a meeting of the Royal Society of Edinburgh. We have seen no mention of the fact elsewhere.

Not only are vowels unaltered by being spoken backwards, but the same fact is true of consonants. Whether the pulsations of air be made in a given order or in the reverse order the ear accepts the sound as indicating the same letter. This is true of all the simple vowel sounds and of all the simple consonant sounds, including of course several combinations which in English are spelt with two letters, as *th* or *ng*, but which are really simple consonants.

We tried the experiment on single pairs of syllables separated by a single consonant, as *ada*, *aba*, *aja*, *etc.* A person coming from outside and ignorant of what consonant had been spoken was able to identify the consonants quite as well backwards as forwards. The chief difficulty was found in distinguishing *affa* from *assa*.

We find that this peculiarity is not limited to consonants between vowels, but that *ab* said backwards becomes *ba*. We have here a standard as to what does really constitute a single letter or element of articulate speech; it is any one reversible part. Your readers who possess a phonograph may most easily verify this observation by saying a word backwards, and hearing the phonograph say it intelligibly forwards; for instance, *noshaeesossa* produces *association* beautifully.

We shall be glad to learn whether this fact has been already published, and also whether it was foreseen as a possibility by any writer.

The Age of the Sun's Heat in Relation to Geological Evidence

1. IT is an admitted fact that the age of the sun's heat will not harmonise with the evidence of geology, on the supposition that this heat was *solely* derived from the approach of matter under the action of gravity. Dr. James Croll, in dealing with this question in a recent number of NATURE,[1] has suggested the existence of a previous proper motion in the colliding matter that formed the sun, whereby, in accordance with accepted physical principles, a store of heat adequate for any period might have been provided. However a difficulty is raised here by Dr. Croll, in the *Philosophical Magazine* (May, 1868), where this question is first dealt with, and as this difficulty would seem on examination not to be insurmountable, I venture to call attention to the subject here, more especially as attendant questions of interest would seem to attach to it.

2. Of course it is admitted that the age of the sun's heat is the limit to conditions of life on the earth, and the point in question is that if the sun had acquired such a store of heat as geological time would appear to demand, then the sun must have been (owing to the excessive heat) a very extensive nebula, probably extending far beyond the limits of the present solar system, and consequently, that even if such a store of heat had existed in the sun, it would not be available for geological time, since the earth could not then have existed as a separate planet, from the fact that the solar nebula would then have extended beyond the limits of the earth's present orbit. Dr. Croll says (p. 372): "But if the sun had originally possessed the amount of energy supposed, then his volume would have extended beyond our earth's orbit, and of course our earth could not at that time have existed as a separate planet." This, therefore, puts a difficulty in the way of the sun having possessed such a store of heat as would be available for geological time. The accepted principles of Laplace are, of course, admitted here, according to which the earth originally formed part of the nebulous mass of the sun, and became naturally detached through the rotation of the nebula at its contraction.

3. Here it seems to have been tacitly assumed (according to the quotations above given) that the present orbit of the earth was its *original* orbit. Is there, however, any necessity for assuming this? For in this lies all the difficulty. Are we not rather warranted in inferring from accepted principles that the present orbit of the earth was *not* its original orbit. For it is an admitted fact that resisting media (the ether, &c.) exist in space, by which, through friction, the orbits of the planets are gradually becoming contracted, so that they slowly approach the sun. It is a mere question of *time*, therefore, for the earth to have come in towards the sun from any distance, or its original

---

[1] NATURE, vol. xvii. p. 206; also *Quarterly Journal of Science*, July, 1877

orbit might (for anything we can say to the contrary) have been beyond the present orbit of Jupiter. However slowly we may suppose the earth to be approaching the sun, yet in the vast epoch of time (which is precisely what is *necessary* in order to harmonise with geological evidence) it may have approached millions of miles towards the sun. There is one point of peculiar harmony here which is worth noticing in connection with this, viz., as the sun cools down or gives out less heat to the planets, so the planets reduce their distance from the sun; thus tending to equalise the heat conditions suitable for life. Thus, although the heat of the sun when first formed may have been enormously greater than it is at present, yet on account of the distance of the planets (including the earth) from it at that remote time, the conditions for life may have been as favourable as now, and thus the first geological changes may have commenced on the earth at that remote epoch when the sun was an incandescent nebula occupying a vastly greater volume than now (perhaps even the volume of the earth's present orbit), or under these conditions any interval of time for life on the earth that geological evidence may require is afforded.

4. There is another point that would appear to be of interest in connection with this subject. The *rate* at which a planet approaches the sun through friction in the media in space would depend (admittedly) on its mass, or would be greater when its mass is less. It follows evidently from this therefore that the great planets, Jupiter, Saturn, &c., must have approached the sun at a slower rate than the earth (or the smaller planets generally). It would follow therefore (more particularly in view of the vast epoch of time demanded by geology) that the *relative* position of the planets must have changed from this cause, that the earth, for example, must at one time have been nearer Jupiter than at present; more especially as the greater velocity of the earth in its present contracted orbit causes greater friction (and thereby brings the earth more rapidly towards the sun). Indeed it is an evident consequence of this principle that it would require only a certain relative *difference* in mass of the planets (or in the length of the elapsed time) to have made the small planets occupy positions *beyond* the larger planets originally, and so the positions of the planets to have been reversed, *i.e.*, the smaller planets *furthest* from the sun, and the larger planets nearest. The tendency of the friction evidently is to arrange the positions of the planets, so that the larger are furthest from the sun.[1] This it may be noted is the position at the present time. We do not of course mean to assume necessarily that there has been an actual reversal in the positions of the planets; all we adduce is that friction must inevitably tend to *change* relative position, when the masses of the bodies are different, and whether the positions are reversed depends therefore on the *time* during which this cause was in operation (and here we are considering especially the vast interval of time required by geology)—the change of relative position being more rapid the greater the relative differences of the masses. Thus it is a known fact that a meteorite approaches the sun or contracts its orbit at an enormously more rapid rate than a planet. It is so far certain that through friction in the medium known to exist in space, the planets (whose masses are different) must have changed to some degree their relative positions, or that the earth (for example) must have been nearer Jupiter at one time than it is now. These it should be observed cannot be regarded as speculations, but rather as deductions dependent on accepted principles.

5. Time may evidently have as great significance in physical as in geological changes, or in giving time its full import great results may follow; and it will be admitted that it is of interest to trace the slow operation of causes into their legitimate results through lengthened time epochs, not confining the attention to the infinitesimally narrow range of human experience.

London, March 21 S. TOLVER PRESTON

English Lake-dwellings and Pile-structures

GENERAL LANE FOX has described the old, and, in some cases, successive pile-works in the peat of Finsbury and Southwark, outside Roman London (*Anthropological Review*, vol. iv. No. 17, April, 1867, pp. lxxi. *et seq.*). Another very interesting case was evidently under Sir C. Bunbury's observation in 1856, near Wretham Hall, six miles north of Thetford, where, in a drained mere, "numerous posts of oak-wood, shaped and pointed by human art, were found standing erect, entirely buried in the peat." Red-deer antlers, both shed and broken from the skull, and also *sawn* off, were found in this peat. (See *Quart. Journ. Geol. Soc.*, vol. xii., p. 356.)

Since writing the above, I have been informed that Mr. W. M. Wylie, F.S.A., referred to this fact in "Archæologia," vol. xxxviii., in a note to his excellent memoir on lake-dwellings. I can add, however, that remains of *Cervus elaphus* (red deer), *C. dama ?* (fallow deer), *Ovis* (sheep), *Bos longifrons* (small ox), *Sus scrofa* (hog), and *Canis* (dog), were found here, according to information given me by the late C. B. Rose, F.G.S., of Swaffham; who also stated, in a letter dated August 11, 1856, that in adjoining meres or sites of ancient meres, as at Saham, Towey, Carbrook, Old Buckenham, and Hargham, cervine remains have been met with: thus at Saham and Towey, *Cervus elaphus* (red deer); at Buckenham, *Bos* (ox) and *Cervus capreolus* (roebuck); at Hargham, *Cervus tarandus* (reindeer).

The occurrence of flint implements and flakes in great numbers in the site of a drained lake between Sandhurst and Frimley, described by Capt. C. Cooper King, in the *Journal* of the Anthropological Institute, January, 1873, p. 365, &c., points also in all probability to some kind of lake-dwelling, though timbers were not discovered.

Lastly, the late Dr. S. Palmer, F.S.A., of Newbury, reported to the "Wiltshire Archæological Society" in 1869, that oaken piles and planks had been dug out of boggy ground on Cold Ash Common, near Faircross Pond, not far from Hermitage, Berks.

T. RUPERT JONES

Selective Discrimination of Insects

AS bearing on the question discussed by "S. B.," and by Mr. Bridgman and others, at p. 163 *ante*, and in previous numbers of NATURE, the following observations may have some interest. One day in the latter part of July, 1877, I took on a flower of red clover (*T. pratense*) an humble-bee (*Bombus Carolina ?*), having the hairs of its body and legs densely dusted with pollen-grains of an *Althæa*, which was in full blossom in the same enclosure, about one hundred feet from the spot where I took the bee.

On the same day and at the same place I attempted to take another *Bombus*, which was ravishing a flower of the same species of clover. It escaped me, and, flying to a distance of about twenty feet, alighted on a flower of a Canada thistle (*Cirsium arvense*), into which it immediately plunged its tongue. After watching it feed for a moment or two, I again attempted to capture it, when it again escaped, and, flying to about the same distance as before, alighted on a flower of a larkspur (*Delphinium Consolida*), and upon my third attempt to take it, it flew away and disappeared.

As to whether insects are attracted by odour or colour, I wish to call attention to an observation of Mr. Crouch, as detailed by Mr. Gosse in "A Year at the Shore." "*Tealia crassicornis* is as good a mimicry of the great dahlias as the *Sagartiæ* are of the daisies." "Even bees are occasionally deceived. Mr. Crouch, when once looking at a fine specimen which was expanded so close to the surface that only a thin film of water covered the disc and tentacles, saw a roving bee alight on the tempting surface, evidently mistaking the anemone for a veritable blossom."

Covington, Ky., U.S.A. V. T. C.

The Telephone as a Means of Measuring the Speed of High Breaks

IN some experiments with an induction coil and wheel break which I have lately been engaged on I have found the telephone useful in determining the number of times per second in which the current is broken.

For this purpose it may be attached to the secondary terminals, or the whole or part of the primary current may be passed through it.

The telephone may also be used generally for determining the speed of electro-magnetic motors by taking advantage of the fact that the current driving them is either short-circuited or broken a definite number of times in each revolution. The telephone wires may in this case be attached at two points some distance apart on one of the battery wires. The note of the telephone gives the number of breaks per second.

Pixholme, Dorking, March 17 J. E. H. GORDON

---

[1] It would seem a rather curious fact to note that those planets which contain within themselves the greatest store of heat (*i.e.*, the large planets), and which therefore would probably be the longest time before they were adapted to the conditions of life, are those which approach the sun the slowest. It is also evident that the fact of the earth being a *small* planet, would tend to augment the difference between the range of its present, and that of its original, orbit.

Meteor

As meteors are rarely seen by day, I write to inform you that I observed one this morning, at exactly 10.20 A.M., not only in broad daylight, but in bright sunshine. I only caught a hasty glance of it as it was disappearing. It was in the eastern side of the sky, descending towards a point in the horizon nearly due north from us, at an angle of about 40°. As we are quite in the country, it could not have been anything else than a meteor. I found that two of our servants had seen it also, and described it as having a tail, which I did not see. JAMES ELLIOT

Goldielands, near Hawick, March 25

The Bermuda Lizard

IN his "Geographical Distribution of Animals" (Am. ed. ii p. 135), Mr. Wallace states, speaking of the Bermudas, that "a common American lizard, *Plestiodon longirostris*, is the only land reptile found on the islands."

Plestiodon longirostris is not a common American species. It is peculiar to the larger islands of the Bermuda Archipelago. It was described by Prof. E. D. Cope (*Proceedings* of the Academy of Natural Sciences, Philadelphia, 1861, p. 313) from Bermuda specimens. It has never been found elsewhere. Its closest affinities are with a West African sp

BROWN GOODE

U.S. National Museum, Washington, January

Landslip near Cork

THE village of Coachford, on the River Lee, sixteen miles from Cork, has been the scene of a curious landslip, or subsidence of soil.

On Wednesday, the 13th inst., a man on his way to work, at about eight o'clock A.M., on going along a path beside a dyke or bank which separates two fields close to the village, noticed a breach in the dyke which had not existed before; and on going to examine, found a deep hole in the earth about a yard in diameter, the depth of which appeared to him to be about a hundred feet, and at the bottom of which he heard the sound of running water. From that time till six o'clock P.M. the hole gradually increased in diameter by the falling in of the sides, until it appeared as I saw it on Sunday, the 17th inst., a conical cavity fifty to sixty feet in diameter and thirty to forty in depth.

The soil is composed of gravel and sand, with a substratum of limestone.

The same thing has evidently taken place several times before in the immediate vicinity of the above-mentioned cavity, as there are no less than seven other similar depressions of various sizes in the same piece of ground, but the formation of none of these is remembered by even the oldest inhabitants of the place.

I should mention that the fields between which the landslip has taken place lie pretty high, and that the River Lee is about half a mile distant. A belief has long existed in the village that a stream, which is supposed to flow into the Lee, runs beneath the place, at some depth underground.

Cork, March 20 J. COOKE

JOACHIM JOHN MONTEIRO

A FEW days ago (NATURE, vol. xvii. p. 391) we recorded the melancholy fact of the death of this enterprising African traveller. We have since been favoured with a few particulars of his life and labours, which appear to us to demand more than a passing word of recognition. His work on "Angola and the River Congo" (Macmillan, 1875) is still fresh in the mind of the public, and has been made doubly interesting through the recent travels of Mr. Stanley. Mr. Monteiro commenced his scientific education at the Royal School of Mines, under the late Sir H. De la Beche, and at the College of Chemistry under Dr. Hoffmann, at both of which places he obtained first-class honours. His first visit to Angola was in the year 1858, when he went to work the Malachite deposits at Bembe, in that province, and also the blue carbonate of copper. This obtained honourable mention in the International Exhibition of 1862. It was while working these deposits at Bembe that the King of Congo came down to pay a visit, and was received with all honours. A very curious letter from this king, asking for a "piece of soap to wash his clothes with," is now in the possession of the British Museum.

It was during his stay at Bembe, and while exploring the country round, that he discovered that the fibre of the *Adansonia digitata* was so valuable for the purposes of making paper, but it was not until 1865 that he returned to the coast for the purpose of developing this extraordinary discovery. He continued to work this enterprise for many years, so as to fully establish the claim of this fibre to being the most valuable natural product for paper-making. Paper made exclusively of this fibre is scarcely to be distinguished from parchment, and it is owing to this remarkable quality that a small percentage of the fibre enables the manufacturer to utilise substances which would be otherwise useless. While at Bembe Mr. Monteiro procured some of the most interesting birds, and although the results of his first collecting were perhaps not so important in regard to novelties as those made later on, the value of this, our first contribution to the avifauna of Inner Angola, will never be underrated by ornithologists. In September, 1866, he accompanied Mr. A. A. Silva, the United States Consul, on an ascent of the River Quanza for the purpose of opening up the country to trade, and the natives were greatly astonished at their first experience of a "smoke-vessel." In April, 1873, he had the brothers Grandy as his guests at Ambriz, and supplied them with beads and goods for the arduous undertaking assigned to them by the Royal Geographical Society, of endeavouring to discover the sources of the River Congo, and of aiding Livingstone should he cross the continent and make for the West Coast. Mr. Monteiro accompanied the brothers Grandy five days inland. He explored the Congo as far as Porto da Lenho, in a steamer belonging to a Dutch house at the mouth of the river; and it was while on this expedition that he met by appointment, and at their desire, nine kings of Boma, whose curiosity he greatly excited by being the owner, as they said, of the first white woman, his wife, they had ever seen, and from her hand the kings were greatly pleased to receive a "dash" or present.

Mr. Monteiro was honoured with the friendship of Dr. Livingstone, who strongly desired him to accompany his expedition as mineralogist, but this wish he could not accede to, owing to his engagements in working out the fibre-scheme on the West Coast. His researches in the natural history of Angola have been of great importance to science. Among the many botanical specimens which he forwarded to England may be mentioned the plant and flowers of *Welwitschia mirabilis*, from which Sir Joseph Hooker was enabled to compile his splendid monograph of this extraordinary plant; besides many parasites, orchids, &c., which have been named after him. Perhaps the most interesting animal discovered by him was the beautiful little lemur (*Galago monteiri*), and the well-known chimpanzee, "Joe," which lived so long in the Zoological Gardens, was also brought to England by him. His second collection of birds was described by Dr. Hartlaub in 1865, and contained many new species, the most interesting of which were a Hornbill (*Tockus monteiri*) and a Bustard (*Otis picturata*), while he also procured a living specimen of the splendid Plantain-eater (*Corythaix livingstonii*) discovered by Dr. Livingstone in the Zambesi country.

Mr. Monteiro's eighth, and, as it has unfortunately proved, his last, visit to Africa, was one to Delagoa Bay, and here he expired, after a severe illness, on the 6th of January last. In company with his wife, who contributed so largely to his natural history collections, at which she worked with equal courage and zeal, he had set himself to develop the mineral and natural products of that Portuguese possession, and had already sent to England many valuable specimens, when his untimely death put an end to all his projects. There can be no doubt that Angola, to the elucidation of the natural history of which Mr. Monteiro contributed so largely, still presents a fine field for the collector, and it is to be hoped that some one will be found who will continue the researches so well instituted by the deceased traveller.

SOUND COLOUR-FIGURES

THE great interest excited by Prof. Bell's telephone and Mr. Eddison's phonograph, in which an elastic disc or membrane faithfully takes up the highly complex vibrations due to sounds of the human voice, has directed renewed attention to the optical methods hitherto employed in studying the motion of resonant media. These have, in important instances, been based on observations of the secondary effects produced by sonorously vibrating bodies. Thus Chladni watched the behaviour of sand strewn upon sounding plates and membranes; König that of gas flames acted on by aërial vibrations. The present article describes an analogous method depending on the colours reflected from slightly viscous liquid films when thrown into sonorous vibration.

The ordinary phenomena called the "colours of thin plates" are sufficiently well known, but a short description of them, taken from a standard work on Physical Optics, may still not be out of place here as a reminder.

"If the mouth of a wine-glass be dipped in water, which has been rendered somewhat viscid by the mixture of soap, the aqueous film which remains in contact with it after emersion will display the whole succession of these phenomena. When held in a vertical plane, it will at first appear uniformly white over its entire surface; but, as it grows thinner by the descent of the fluid particles, colours begin to be exhibited at the top, where it is thinnest. These colours arrange themselves in horizontal bands, and become more and more brilliant as the thickness diminishes; until finally, when the thickness is reduced to a certain limit, the upper part of the film becomes completely black. When the bubble has arrived at this stage of tenuity, cohesion is no longer able to resist the other forces which are acting on its particles, and it bursts."—(Lloyd's "Wave-Theory of Light," p. 100.)

If the film, instead of remaining at rest, is thrown into sonorous vibration, totally distinct colour-phenomena instantly present themselves. A rough idea of their general character may be obtained without the aid of any apparatus as follows. While washing the hands, after getting a good lather, a film can easily be formed between the thumb and forefinger of one hand held in a horizontal plane; the other hand supplies an extemporised tube through which a note can be sung, and so vibrations caused to impinge on the *lower surface* of the film.

If this is done the reflected colours will be seen to be in regular motion, and, in particular, a number of small eddies of colour will be observed whirling about fixed centres of rotation. Steady coloured bands may also be sometimes recognised, but with much greater difficulty.

Fixed bands and stationary vortices form, in fact, the constituent elements of all the sound colour-figures obtainable by film-reflection.

In order to study these in detail a specially arranged apparatus is, of course, requisite. I have found the following give excellent results.

An L-shaped cylindrical brass tube is permanently fixed upon a wooden stand, with its two limbs vertical and horizontal. The vertical limb terminates in a narrow flat circular ring. The open orifice of the horizontal limb is fitted into a caoutchouc tube of equal bore, ending in a trumpet-shaped mouth-piece. For the purpose of supporting the films operated on, I use a series of metallic discs pierced with apertures of various shapes and sizes. On covering one of these, by means of a camel-hair brush, with some weak solution of soap,[1] a film of considerable durability will be formed upon it. The disc should first be held in a vertical plane until the coloured bands have begun to show themselves, and then laid gently upon the horizontal ring prepared for its reception. The observer places himself so as to get a good view of the assemblage of colours reflected by the film, and the instrument[2] is ready for use. Sounds of tuning-forks, whistles, organ-pipes, &c., or notes of the human voice have only to be produced near its mouthpiece, in order that their vibrations may be conducted to the film, and the resulting phenomena observed.

The forms thus presented are of endless variety and great beauty. They almost invariably include both motionless curvilinear bands of colour very regularly disposed, and also a system of colour-vortices revolving about fixed nuclei. The contrast between the steady and moving portions of the figures is always very striking, and the effects of changing tint which accompany the progressive thinning of the film gorgeous in the extreme. When the moment of its dissolution is close at hand, patches of inky blackness invade the field, until at last there is sometimes nothing left but an ebony background, with here and there a few scraps of light, either at rest or still flying round their former orbits, the remnants of fixed bands and whirling vortices.

That the results obtainable by the mode of experimenting above described are likely to present a practically endless variety of form, will be at once obvious from an enumeration of the several causes which may influence the assemblage of colours reflected at a given instant from a given film acted on by the vibrations of a given sound. These are:—1. The shape of the film; 2. Its size; 3. Its consistency; 4. The intensity of the sound; 5. Its pitch; 6. Its quality; 7. The direction in which the sound-vibrations take place with reference to the plane of the film.

It thus appears that each colour-figure observed *may* be a function of not less than seven[3] independent variables; and on experiment this proves to be the fact. An alteration made in any one of these elements, while all the rest are kept constant, produces a corresponding change in the appearances observed. The intensity of the sound does not, it is true, affect the form of the figure, but controls the rate of its vortical motion; the louder the sound the more rapid the rotation of the colour-whirls. All the other elements act directly on form.

It is evident from what has preceded that an attempt at anything like a general classification of sound colour-figures would afford materials for a considerable volume. All that can be done within the present narrow limits is to draw attention to a few points of special interest.

Dependence of Form on Pitch.—This is perhaps most distinctly shown by alternately stroking with a resined bow two mounted tuning-forks of different pitch, the open ends of whose resonance-boxes are placed close to the mouthpiece of the Phoneidoscope. As long as the same aperture is used, and the film kept at one degree of consistency by frequent renewal, each note will instantly call forth its own colour-figure for any number of alternations. This mode of experimenting has the advantage of giving perfectly steady and sharply defined figures. But the successive alterations of form due to changing pitch are more interestingly shown by singing[4] the diatonic or chromatic scale, on some single vowel, into the Phoneidoscope. The complete change of figure consequent on perhaps but a semitone's alteration of pitch, is often most surprising. It was these sudden kaleidoscopic bounds from one form to another which suggested the name given to the observing instrument. In general the complexity of the figure increases with the acuteness of the exciting sound. With low notes a comparatively simple arrangement of a few rings and pairs of vortices occupies the film. As the pitch rises, the separate parts of the figure diminish in size and increase in number, so that the whole field is covered with a regular pattern which is constantly growing more and more minute. With very shrill sounds the pattern can only be made out by using a magnifying-glass.

---

[1] Castile soap, I find, answers extremely well.

[2] It is manufactured and sold under the title of the "Phoneidoscope," by S. C. Tisley and Co., Philosophical Instrument Makers, 172, Brompton Road, S.W.

[3] A reader of Helmholtz will see that I might have added an eighth element by taking into account differences of phase among partial tones, which, though inoperative on quality, directly affect mode of resultant vibration.

[4] A pitch-pipe with a sliding piston may be substituted for the voice in this experiment.

Effects of Quality.—These are easily observed by employing unison organ-pipes of different *timbres*, *e.g.*, treble C's belonging to stopped and open diapasons, claribella, and hautbois, respectively. By sounding them consecutively in the above order, figures rapidly increasing in complexity are obtained.

Prominent among differences of quality are those which distinguish vowel-sounds of the human voice sung successively on one and the same note. Marked corresponding differences of colour-figure are recognisable in many instances, but I have not at present succeeded in extending the observation to *all* the European vowel-sounds.

Effects due to Direction of Vibration.—The best mode of observing these is to strike a tuning-fork, and hold it with one of its prongs *close* to the surface of the film.

By moving the fork it is easy to show that both the axis of symmetry, and to some extent also the form, of the colour-figure thus produced, are dependent on the position of the fork with respect to the film, and therefore on the direction in which the exciting vibrations impinge upon it. The steady bands of a figure obtained by this method shift to and fro upon the film in obedience to the fork's movements, almost as though under a magnetic influence resident in its prongs.

Resultant Figures due to Combined Sounds.—If the sounds of two tuning-forks are separated by a considerable interval of pitch, say an octave, they will generate, when alternately applied to the same film, very different figures. When both are applied together there results a figure different from either of those due to each fork by itself. It is in fact a compromise between the two. In order to convince himself of this the experimentor should first get the forms of the component figures well into his memory by repeatedly producing them, and then watch the effect, *on some one band in either figure*, of mixing the two sounds in various degrees of relative intensity. Let us suppose that fork 1 produces figure 1, and fork 2 figure 2, respectively, and that a band in figure 1 is selected for observation. Then if fork 1 be struck sharply, and fork 2 weakly, the band will alter its form so as to exhibit a slight approach to the arrangement in the corresponding part of figure 2. As the note of fork 2 is more loudly sounded this approach will be more decided. If fork 2 is made preponderant the result will be the arrangement of Fig. 2 with some modification towards that of figure 1. The same thing holds good for the rotating portions of the figures. Complex colour-flows are seen to result from a compromise between simpler component vortices.

Effect of Beats.—When two sounds of very nearly the same pitch coexist, slow fluctuations of intensity called "beats" are known to be produced. If a film is exposed to the simultaneous action of two sounds so related, the fixed parts of the resulting figure take up a swaying motion about their mean position, each complete oscillation synchronising exactly with one entire beat. The vortices show, in general, an increased speed of rotation during one half of each beat, and a diminished speed during the other half. But in particular cases a bolt forward every alternate half-beat seems to be followed by intermediate quiescence, or the direction of motion may be actually reversed, so that a vortex rotates positively during one half-beat and negatively during the next.

Representation of Dissonance.—When the beats become too rapid for separate recognition, and coalesce into the effect which we call discord, the colour-figure presents a tremulous appearance, like that shown by the tip of a singing gas flame. Prof. Helmholtz has remarked how unpleasant is the impression which a flickering light makes upon the eye, and pointed out its analogy to the effect of rapidly intermittent sounds on the ear. In the present experiment, acoustical and optical dissonance are exhibited in a direct and interesting connection.

As the phenomena described in the above article admit of such facile reproduction in all their beauty of form and splendour of hue, I have thought it needless to attempt illustration by diagrams, which could convey but an inadequate notion of the former, and none at all of the latter. REFLECTION OF LIGHT[1]

PLACE the heliostat in position, and bring a slender beam of light into the darkened room. Then get a small looking-glass, or hand-mirror, and a carpenter's steel square, or a sheet of stiff paper, having perfectly square corners. Hold the mirror in the beam of light. At once you see there are two beams of sunlight, one from the heliostat and another from the mirror. Hold the glass toward the heliostat, and you will see this second beam going back toward the window.

This is certainly a curious matter. Our beam of light enters the room, strikes the mirror, and then we appear to have another. It is the same beam, thrown back from the glass. This turning back of a beam of light we call the reflection of light.

Fig

Place a table opposite the heliostat, and place the mirror upon it, against some books. Turn the mirror to the right, and the second or reflected beam of light moves round to the right. Turn the glass still more, and the beam of light will turn off at a right angle, and there will be a spot of light on the wall at that side of the room. Now bring the carpenter's square or the piece of square paper close to the mirror, so that the point or corner will touch the glass just where the sunlight falls upon it. Now one edge of the square is brightly lighted by the sunbeam, and if the mirror is placed at an angle of forty-five degrees with the sunbeam, the other edge of the square is lighted up by the second beam.

---

[1] From a forthcoming volume of the "Nature Series"—"Light: a Series of Simple, Entertaining, and Inexpensive Experiments in the Phenomena of Light, for the Use of Students of Every Age," by Alfred M. Mayer and Charles Barnard.

In Fig. 1, A is the beam of light from the heliostat, and B is the beam reflected from the mirror, that is marked M. To make this more simple, we call the first beam the beam of incidence, and we say that it travels in the direction of incidence, as shown by the arrow. The second beam, marked A, we call the beam of reflection, and the course it takes we call the direction of reflection. The point marked O, where the light strikes the mirror, is called the point of incidence.

In the diagram is a dotted line representing a quarter of a circle reaching from the beam of incidence to the beam of reflection. A quarter of a circle, as you know, is divided into ninety degrees. Another dotted line extends from O at the mirror to X on the quarter-circle, and divides it into two parts. Half of ninety is forty-five, and hence the mirror stands at an angle of forty-five degrees with both beams of light. Now the line A and the dotted line reaching from O to X make the angle of incidence, and the angle between B and the line from O to X is the angle of reflection; and the curious part of this matter is, that these two angles are always equal. Here they are both angles of forty-five degrees.

Move the mirror about in any direction, and measure the angles of incidence and the angles of reflection, and these angles will always be exactly equal.

If you look at the diagram you will see that the mirror is at an angle of 45 degrees with the beam of incidence, and that the beam of reflection is at an angle of ninety degrees with the incident beam. Hence, if the mirror is tilted through a certain angle, the reflected beam is tilted through twice this angle. For instance, if the mirror is moved 1 degree, the beam of reflection moves 2 degrees. Place the mirror at an angle of 22½ with the beam of incidence, and the beam of reflection is at angle of 45. Move the mirror to an angle of 67½, and the beam of reflection will move round to an angle of 135 degrees.

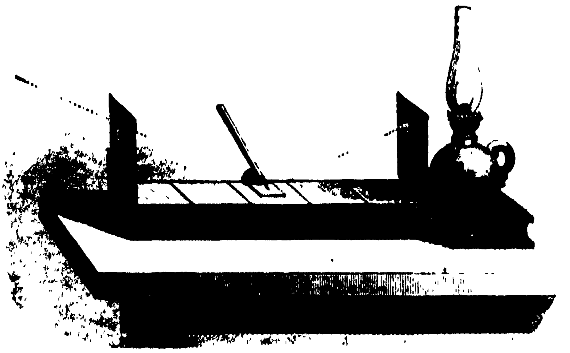

FIG. 2

Fig. 2 represents the two postal-cards fitted on blocks of wood that we used in a former experiment, and the three blocks of wood we cut out at that time. The five blocks are placed close together in a line, and with the postal-cards at the ends. A lighted lamp is placed near one of the cards, and on the middle block is a small piece of window-glass that has been painted with black varnish. A single coat of black varnish on one side of the glass is all that is required to give us the black mirror needed in this experiment. Place the lamp close to the card in such a position that the flame will be just on a level with the hole in the card. If the lamp is not convenient the blocks and cards may be placed upon a table facing a north window in full daylight.

When everything is ready look through in the postal-card marked B, down upon the black mirror, and on it you will see a single spot of light, the reflection from the lamplight or the light from the window shining through the hole marked A in the drawing. Get the needle-pointed awl and place it so that the point will just touch the spot of light in the black mirror, and then fasten the awl in this position with a piece of wax, as represented in the picture.

You will readily see that this experiment is the same as the last. Again we have a beam of light reflected from a mirror. The beam of incidence passes through the postal-card at A and finds its point of incidence on the mirror, and the beam of reflection extends from the point of incidence to the second card at B.

Take a sheet of stiff paper 10 inches (25·4 centimetres) long, and about 4 inches (10 centimetres) wide, and hold it upright between the two cards, with the bottom resting on the mirror. With a pencil make a mark on the edge of this at the point of incidence marked by the awl, and at the hole in the card where the beam of incidence enters, and marked A in the drawing. Draw a line between these two points and you have an angle formed by this line and the base of the paper. This angle marks the angle of incidence. Put the paper on the blocks with the ruled line toward the card B, and you will find that the line fits here equally well. It now extends from the point of incidence to B, and proves that this angle is the same as the other, that both sides are alike, and that the angle of incidence and the angle of reflection are equal.

Take out the block in the middle and move the others nearer together till they touch. Repeat the experiment: make a measurement with a piece of paper as before, and draw a line on it from the point of incidence to either of the holes on the cards, and then compare the angles thus found, and in each case they will be exactly alike. Take out another block and try it again, and you will reach the same result.

These experiments show us that there is a fixed law in this matter, and the more we study it the more we are convinced that it has no exceptions.

Experiment in Multiple Reflection

Choose a south room on a sunny day and close the blinds and shutters at all the windows save one, and at this window draw down the curtain until only a narrow space is left at the bottom. Close this space with a strip of thick wrapping-paper, and then cover the rest of the window with a blanket or shawl so as to make the room perfectly dark. Then cut a round hole the size of a five-cent piece in this paper, and through this hole a slender beam of sunlight will fall into the darkened room.

Bring a hand-mirror into this beam of light and the beam of reflection will make a round spot of sunlight on the wall above the window. This spot of light is a picture of the sun thrown by the mirror upon the wall. Hold the mirror at an oblique angle in the sunbeam and direct the beam of reflection upon the opposite wall. Now there are several reflections, brilliant spots of light. If the spots of light do not stand out sharp and clear, turn the mirror slowly round and you will soon find a position for the glass that will give six or more reflections.

How does it happen that a common looking-glass can thus split a single sunbeam into several beams? If you touch a pencil to a mirror you will notice that while the point of the pencil touches the glass the point of the reflected pencil seen in the mirror does not meet the point of the real pencil, and that there is a little space between them. The reflection we see in the glass is from the smooth surface of the quicksilver at the back of the glass, and the space between the reflection and the pencil is filled by the glass.

Hold a sheet of common window-glass before a lighted lamp or candle, and you will see a faint reflection of the flame in the glass, and at the same time you can readily see through the glass. This shows us that the outside any piece of smooth glass will reflect light, and our experiment is designed to show a still more curious matter.

Fig. 3 represents the single beam reaching the point of incidence on the outside of the mirror at O, and reflected to the wall at 1. Part of the light goes through the glass to B, and here is another point of incidence, and a new beam of reflection is thrown through the glass to the wall at 2. If you look at the reflections on the wall, you will see that the second spot of light is the brightest. This comes from the quicksilver, for, as this is a better reflector than the glass, it sends out a brighter beam of reflection. When this second beam of reflection passes through the glass, a part of its light is reflected from the under side of the surface, and is turned back against the quicksilver again. Once more it is reflected, and a new beam of reflection makes number 3. The drawing shows the path these beams of light take in the glass, and the quivering spots of light on the wall show how one beam of light may be reflected again and again in different directions. If the reflector was perfect and returned all the light, these multiple reflections might be repeated many times over; but every time light is reflected from any bright surface a part of the light is lost, and thus each reflection grows fainter and fainter till the light is spent. Look at the multiplied reflections on the wall, and you will see that the first reflection from the glass is bright, and that the second, from the quicksilver at the back of the glass, is brighter still; and that the others grow fainter and fainter till all the light is spent, and the reflections disappear.

FIG.

Second Experiment in Multiple Reflection

Light a lamp and place it on a table, and get the two postal-cards and the blocks that we used in the experiment in reflection. With a sharp knife cut a slit in one card, just at the pin-hole, about ¾ inch (19 millimetres) long and $\frac{1}{25}$ inch (1 millimetre) wide. Then place this card close to the lamp, as in the other experiment, and set up the other card about fifteen inches away from it. Then lay a looking-glass on the table between the two. Look at Fig. 2, and arrange the cards as there represented, and put the mirror in place of the blackened glass on the blocks. On looking through the small hole in the postal card (marked B in the drawing), you will see in the mirror several bars of yellow light, placed one over the other. Again we have an instance of multiplied reflection. Instead of seeing the reflections thrown upon the wall, we can look down upon them and see them, just as they stand, each at its point of incidence on the glass and the quicksilver. Study these brilliant bars of light, examine the diagram carefully, and you will readily see that this experiment simply exhibits in a different manner the same thing that we saw in the last experiment.

Experiment with Mirror on Pulse

Get a small bit of looking-glass, about an inch (25 millimetres) square, and some wax. Warm the wax in the hand till it is soft, and then make three small pellets about the size of a pea. Put one of these on the back of the little mirror, near the edge and half-way between two corners. Place one at each of the opposite corners, so that the mirror will have three legs or supports placed in a triangle. Put the heliostat in place, and bring a small beam of sunlight into the dark room. If this is not convenient any beam of sunlight in a dark room (as in former experiments) will answer.

Turn back your coat-sleeve, and, while standing near the beam of light, place the little mirror on the wrist, with one of the wax legs resting on the pulse. Then bring the arm into the beam, so that the light will fall on the mirror. Hold the arm steady, and watch the spot of reflected light thrown upon the wall. See! It moves backward and forward with a curious, jerking motion. It is like the ticking of a clock, or like the bending of one's pulse. It is the motion of your pulse. The mirror moves with the pulse, and the beam of reflection thrown on the wall moves with it, and, though this movement is very slight, the reflection on the wall moves over a space of several inches, and we can see it plainly. In our first experiment in reflection we learned that when a mirror was moved to the right or left, the beam of light reflected from it moved also to the right or left, and each time through twice as great an angle as the mirror.

This experiment is a wonderfully interesting one, and may be tried with a number of boys or girls, and each may see the peculiar beating of his or her pulse pictured on the wall in the most singular and startling manner. If any of the persons whose pulse-beats are thus exhibited get excited, laugh at the exhibition, or are in any way disturbed, the change in the movement of their pulse will be quickly repeated on the wall, where a hundred people can see it.

Experiment with Glass Tube

Procure a glass tube, about ¾ inch (19 millimetres) in diameter and 12 inches (30·5 centimetres) long, and paint the outside with black varnish. If this is not convenient, cover the tube with thick black cloth, and fasten it down with mucilage, taking care to have the cloth square at the ends. Punch a hole in a postal-card with the sharp point of a pair of scissors, and with a knife make the ragged edges of the hole smooth. Hold the card at one end of the tube so that the hole will come just at the centre of the opening, and then, while facing a window or a bright lamp, look through the tube with one eye, and you will see a spot of light surrounded by a number of beautiful rings.

Here we have another example of multiplied reflection. The light entering the tube through the hole in the card falls on the smooth surface of the interior of the tube, and appears to the eye in the form of rings.

Fig. 4 represents a section of the tube, and shows the paths the different rays of light take, and shows how each is reflected from side to side till they all meet in the eye. The dotted lines and the rings projected beyond the tube show how they appear to the eye. By studying this drawing carefully, and trying cross cuts and slits in the card in place of the single hole, you will get a very correct idea of repeated reflection, and find the tube a source of considerable amusement.

Experiments in Dispersed Reflection

Get a small piece of black velvet or cloth and take it to a dark room where the heliostat will give us a slender beam of sunlight. If this is not convenient use a common beam of sunlight in a dark room, as in some of our former experiments. Hold the velvet in the hand between the fingers, and so as to leave the palm of the hand clear. Turn back the coat-sleeve so as to expose part of the white cuff, and then bring the velvet into the beam of sunlight. You will observe nothing in particular, for the black rough cloth does not reflect the light at all. Now move the hand so that the spot of light will fall on the palm. See what a pretty rosy glow of light falls on the wall! This is the reflected light from the hand. The skin is rough, and the light is diffused and scattered about, and instead of a bright spot of reflected light, as with a mirror, we have this glow spread all about on the wall and furniture. Now move your hand so that the sunlight falls on your cuff. Immediately there is a bright light shining on the wall and lighting the room with a pale bluish-white glare. Move the hand quickly so that the black cloth, the hand, and the white cuff will pass in succession the beam of light. Observe how the different things reflect the light in different degrees. The cuff is the smoothest and whitest, and gives the brightest reflection; the hand gives less light because it is less smooth; and the cloth, that has a very dark and rough surface, gives no reflection at all, and the spot of sunlight falling upon it seems dull and faint.

This experiment shows us something more in the reflection of light. A piece of glass, the surface of water, polished metals, ice, and all substances having very smooth surfaces, reflect light in one direction. The linen cuff also reflected light, but apparently in a very different manner from the mirrors we have been using.

Place a lighted lamp upon a table and lay a mirror before it, and you can see a clear and distinct reflection of the lamp and the flame pictured on the glass. Put a sheet of white paper before the lamp, and you can see only a confused spot of reflected light on the brightly-lighted paper. Lay a freshly-ironed napkin or handkerchief before the lamp, and even the indistinct spot of light has disappeared, and the white cloth reflects light equally from every part.

These drawings are intended to show how light is reflected from different surfaces. The first represents a smooth surface, like glass, that sends all the beams in one direction, because the points of reflection for the beam are in the same plane. (See 1, 2, 3, Fig. 5.)

The second drawing represents a slightly-roughened surface, like paper. Some of the points of reflection turn the light one way, some another, and the beam of reflection is no longer formed of parallel rays. They are scattered about, and the image they form is confused and indistinct. In the third drawing we have a rough surface, like cloth, and here the rays of the beam of reflection are scattered in every direction, and we can see no image.

It is in this manner that we are enabled to see the people and things about us. The light of the sun or a lamp falls upon them, and is reflected into our eyes, and we say we see the objects. Very few things reflect light so brightly that we obtain from them a reflected image of the source of the light, and we generally see only dispersed and scattered light, that does not blind or dazzle the eye, and enables us to look upon these objects with ease, and to readily see all their parts.

The clouds, the water, the grass, rocks, the ground, buildings, the walls inside, clothing and furniture, and everything we can see, reflect light in every direction again and again, and thus it is that all spaces, without and within, are filled with light so long as the sun shines. At night the sun sinks out of sight, and still it is light for some time after, for the sunlight is reflected from the sunset-clouds and the sky.

Sometimes, upon a summer's day, when broken clouds partly hide the sun, you will see long bars of dusky light streaming from openings in the clouds. These long bars are beams of sunlight shining upon dust and fine mist floating in the air, and we see them because each speck and particle reflects light in every direction.

Experiment with Jar of Smoke

Fig. 6 represents a large, clean glass jar, such as one sees at the confectioner's. It is standing upon a black cloth laid upon a table in a dark room, and on top of the mouth is laid a postal-card, having a slit, one inch (25 millimetres) long, and $\frac{1}{25}$ inch (1 millimetre) wide, cut in it. Above the jar is a hand-mirror, so placed that the beam of sunlight from the heliostat (or from a hole in the curtain) will be reflected downward upon the postal-card on top of the jar.

This simple apparatus is designed to show how light is reflected from small particles floating in the air. Set fire to a small bit of paper and drop it into the jar. Place your hand over the mouth of the jar, and in a moment it will be filled with smoke. When the paper has burned out, put the postal-card in place, so that the slit will be in the centre of the mouth of the jar. Let the beam of reflected light from the mirror fall on this slit.

Look in the jar and you will see a slender ribbon of light extending downward through the jar. Elsewhere it is quite dark and black. Here we see the light streaming through the opening in the card, and lighting up the particles of smoke in its path.

Take off the card, and let the reflected beam fall freely into the jar. The smoke is now wholly illuminated, and the jar appears to be full of light, and every part of the bottle shines with a pale-white glow.

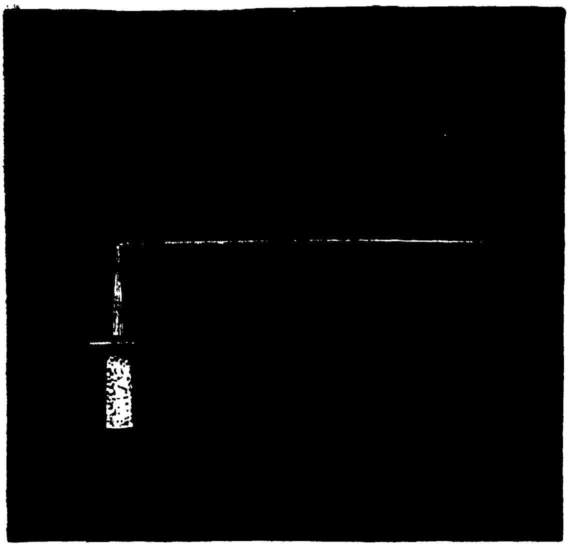

Fig. 6

Put the postal-card on again and let the light fall through the slit. The smoke has nearly all disappeared, and the ribbon of light in the jar is quite dim. Curious streaks and patches of inky blackness run through it. What is this? Nothing--simply nothing. The smoke is melting away, and the beam of light disappears because there is nothing to reflect it and make it visible.

This part of the experiment appears quite magical in its effects, and is exceedingly interesting.

The Milk-and-Water Lamp

Take away the jar and put a clear glass tumbler in its place. Fill this with water and throw the beam of reflected light down upon it, and the water will be lighted up so that we can easily see the tumbler in the dark. Now add a teaspoonful of milk to the water and stir them together. Throw the beam of light down once more. This is indeed remarkable. The tumbler of milk-and-water shines like a lamp, and lights up the room so that we can easily see to read by its strange white light. Move the mirror and turn aside the beam of light, and instantly the room becomes dark. Turn the light back again, and once more the glass is full of light.

Here the minute particles of milk floating in the water catch and reflect the light in every direction, so that the entire goblet seems filled with it, and the room is lighted up by the strange reflections that shine through the glass.

AMERICAN GEOLOGICAL SURVEYS

MISSOURI

THE State of Missouri boasts of abundant mineral wealth. Its seams of coal and its stores of iron and lead mark it out as one of the great centres of the future industry of the United States. Such a country might have been supposed only too anxious to have its mineral formations accurately mapped, so as to know exactly where and how its subterranean resources lie. Yet the history of its official action in this matter is by no means a gratifying one. As far back as the year 1849 a memorial was presented to the General Assembly of the State, praying for the formation of a Geological Survey, with liberal appropriations for constructing maps and publishing reports; for investigating causes affecting health, the agricultural capacities of different soils, the water system, and the rocks and minerals of the country. It was not until the early summer of 1852 that the State geologist, who, in response to this memorial, was appointed, began operations. Five annual reports, consisting for the most part of only a few leaves, appeared up to the year 1861, and, with one exception, contained mere statements of progress. Perhaps the Legislature began to think that the results obtained were not worth the expenditure to secure them. At all events, in 1861 the Survey was disbanded. The authorities, however, seem to have been unwilling that the fruits of the long years of work of their geological staff should be lost; they accordingly arranged to have them published, but finally abandoned this idea on account of the expense. For nine years nothing further appears to have been done in the matter. At last, in 1870, the Legislature once more roused itself to consider the expediency of having the country properly explored and mapped. A "Mining, Metallurgical, and Geological Bureau" was now created, and a new State geologist was appointed. This arrangement, however, not proving satisfactory, the act was amended next year, but soon thereafter the State geologist resigned, and Mr. R. Pumpelly took his place. The body by which the geological work of the State was controlled, now called the "Bureau of Geology and Mines," consisted of a board of five managers, with a staff formed of a State geologist, an assistant palæontologist and geologist, an assistant chemist, and such additional assistance as might be possible within the limits of an annual appropriation of 10,000 dollars.

By the spring of 1872 a more liberal spirit had appeared in the assembly. An additional chemical assistant was allowed, and the annual vote was raised to 20,000 dollars. The Survey now set to work with prodigious vigour. Mr. Pumpelly and his associates undertook an extensive exploration of the iron and coal districts, while the chemists were busy analysing the minerals sent into them from the field. By the end of the year a large mass of information had been collected, and as the liberality of the Legislature had shown no sign of waning, a large appropriation was asked for the publication of the results obtained in 1872, and another grant for the issue of the still unprinted reports of previous years. Both these appropriations, amounting to 9,000 dollars in the one case, and 3,000 dollars in the second, were voted. Accordingly two volumes duly appeared next year. The Report for 1872 was sumptuously printed and illustrated. Moreover, it was accompanied by a monstrous atlas of chromo-lithograph maps and sections. Some parts of the coal-fields were carefully illustrated by sections to show the structure of the areas and the relative positions of the seams in different districts. Perhaps some of these sections were on a needlessly large scale. Certainly the whole atlas was issued in a style so luxurious as to suggest that the Legislature must not only have become more liberal, but must be anxious to atone for former delinquencies by an almost extravagant expenditure in print and paper.

But this golden age was not destined to last. Mr. Pumpelly resigned, very shortly after the appearance of his meritorious though costly volumes. His successor, Mr. G. C. Broadhead, who had previously acted as chief assistant-geologist, found the fund at his disposal so depleted by the heavy expenses of the winter and spring of 1873, that he had to reduce his field-staff. The Board of

Management likewise determined that the cost of the Annual Reports should in future be paid out of the yearly appropriation, thereby of course, considerably narrowing the possible amount of work to be done in the field. In spite of these drawbacks, however, the State-geologist succeeded, during his first year of office, in doing some useful work, and yet kept a sufficient balance to publish a bulky report with a quarto atlas of plates. His plan was to attack first of all those branches of inquiry which presented the greatest interest or had the closest bearing upon the industrial resources of the State. The ground was surveyed by counties, Mr. Broadhead himself taking a lion's share of the hard work. The two lead regions of Southwest and Central Missouri were likewise examined. Many analyses were also made of the ores, slags, coals, and other mineral substances sent up to the office. The Report which gave an account of these labours cannot fail to be of great service in the development of the mineral resources of the State. Mr. Broadhead is evidently exactly the kind of director needed to keep the Missouri Geological Survey in full activity and to satisfy the demands of a utilitarian legislature.

The oldest rocks in Missouri appear to be certain granites and other crystalline masses, on which lie somewhere about 3,000 feet of Lower Silurian strata, including representatives of the Potsdam, Black River, Birdseye, Trenton, and Cincinnati groups of other parts of the United States. Upper Silurian rocks are much more feebly represented, but Dr. Shumard has recognised beds probably equivalent to the lower Helderberg and Niagara groups. The Devonian groups of Hamilton and Onondago are still more sparingly developed, only about 100 feet of strata being referable to those horizons. The Carboniferous system, however, is well displayed, and contains the following groups :—

LOWER.	Upper coal-measures (poor in coal)	1,307 feet
	Middle ,, (with 7 ft. of coal)	324 ,,
	Lower ,, (with 13 ft. 6 in. of coal) ...	250–300 ,,
UPPER.	Chester group (sandstone) from a few feet to ...	100 ,,
	St. Louis ,, (limestone), maximum	250 ,,
	Keokuk ,, (shale and chert), perhaps exceeding	200 ,,
	Encrinital or Burlington group	60 ,,
	Chouteau limestone	100 ,,
	Vermicular sandstone and shales	75 ,,
	Lithographic limestone	55 ,,

No later formations occur until we reach the "Drift. This consists of two divisions ; the lower, formed of dark blue clay, overlaid and interstratified with beds and pockets of sand sometimes inclosing remains of terrestrial vegetation ; the upper composed of stiff, tenacious, brown, drab, and blue clays, often mottled, and containing rounded granitic pebbles. Large boulders of crystalline rocks from a northern source occur in the lower division, up even to a height of 1,050 feet above the level of the Gulf of Mexico. Most of the observed boulders occur in the valleys. They diminish in numbers and size as they are traced southwards, the Missouri River seeming to limit their extension in that direction. Above these clays lies the "bluff," or loess, a very fine light brown siliceous marl, with occasional concretions of limestone. With sufficient consistency to weather out into perpendicular escarpments, this deposit forms a belt of hilly country receding ten miles from the river, and then changing into a stiff clay which may be part of the "drift." The low alluvial lands lie on what is termed the "bottom prairie," generally a dark tenacious clay, often containing concretions of bog-iron, and rarely beds of sand.

From the early part of last century lead and iron have been worked in Missouri. The mining industry of the State has gradually developed, and is now making rapid progress. In the year 1872, 13,550,135 pounds of lead were produced in the State. During the first six months of 1874, 5,050 tons of pig-lead were sent by railway into St. Louis. The yield of iron and zinc is likewise steadily increasing. Vast quantities of sulphate of baryta are said to be raised, and to be used in the improvement (that is, the adulteration) of white lead. A territory so richly stored with mineral wealth ought to be able to equip and maintain a sufficient staff for the thorough exploration of the geological and mineralogical structure of the ground, and for the formation of a museum where the rocks, minerals, fossils, and manufactured mineral products may be displayed, and made practically useful and instructive.

ARCH. GEIKIE

OUR ASTRONOMICAL COLUMN

DUN ECHT OBSERVATORY PUBLICATIONS, VOL. II.—In this handsomely-printed volume of two hundred pages we have the first portion of results of observations made during Lord Lindsay's expedition to the Mauritius on the occasion of the late transit of Venus, an expedition which for the care and forethought bestowed upon the arrangements and the excellence and completeness of the equipment, compares favourably with any of those fitted out by the various Governments which took part in the observation of this rare phenomenon.

It was upon the strong recommendation of the eminent Secretary of the German Transit of Venus Commission, Prof. Auwers, that Lord Lindsay was induced to take out a heliometer, and an instrument of this class, similar to those intended to be used in the Russian expeditions, was ordered in the spring of 1872 and completed in due time by the joint exertions of Messrs. Repsold, of Hamburg, and Messrs. Cooke and Sons of York. In the investigation of the constants of the instrument previous to the expedition, experience was obtained of the great precision to be attained in the measurement of angular distance between two stars by its means, and this experience led to a determination to take advantage of a near opposition of the minor planet Juno, occurring during the anticipated period of residence at the Mauritius, to investigate the solar parallax, from the diurnal parallax of the planet, by measuring its distance and angle of position with respect to a star, both morning and evening. On November 4 Juno in perigee was distant 1·029, and though the parallactic displacement in such case is considerably less than in a transit of Venus, or an opposition of Mars, it was believed that the great accuracy attained in measures with the heliometer would more than compensate for this disadvantage.

Vol. ii. of the publications of Lord Lindsay's Observatory is devoted to the discussion of the observations of Juno, preceded by a very detailed account of the instrument and its adjustments and of the methods adopted in determining its instrumental errors, as errors of scale divisions and errors of screw and of the method of observation and calculation of instrumental results. And in the event of criticism of any of the processes it must be stated that the whole of the work is so presented as to admit of future discussion, with any modification of plan that may be deemed advisable. It was originally intended that the observations should commence on October 10 and continue to the end of November. Circumstances, however, prevented so long a series of measures ; Lord Lindsay's yacht with the instruments did not arrive at the Mauritius until November 2, and it was not till November 10 that the first heliometric observations could be made. The first reliable series was obtained two evenings later, and from this time to November 30, observations were secured on twelve evenings and eleven mornings, some of them not being so complete as was desirable. It will thus be seen that Juno was past opposition before work could be commenced, and this first attempt to determine the solar parallax, through measuring the diurnal parallax of a minor planet with the aid of the heliometer, was consequently made under less favourable conditions than may be secured in future investigations of the same kind; nevertheless, it is certain that Lord Lindsay and Mr. Gill have been amply justified by the result in the confidence they placed upon the proposed methods of observation, and have proved that one means of determining the solar parallax, admitting comparatively of very frequent repetition, is comparable in point of accuracy with methods involving far greater difficulty and expense and chance of failure. In the correction of the equations of condition for errors in the tabular places of Juno, derived from observations at Greenwich, Washington, and Cambridge, U.S., it was found desirable to work upon two systems, the probabilities being rather in favour of the second. The definitive result for the mean solar parallax is 8″·77, according to the first system, and 8″·76 according to the second. To these values and their probable errors (± 0″·04) the authors do not attach high importance, indeed, a discordant value from observations on November 15 being included, they say, "if we were asked what we believe to be the most probable value resulting from the determination, we should reject this result; the values then become 8″·82 — first system; and 8″·81 – second system. At the same time we are aware that the rejection of any observation is quite unsound." In a longer series, however, it is probable, as they observe, that the single discordant value would have been counterbalanced by another.

So far as we know, this is the first application of the heliometer to observation in the southern hemisphere. We think it must be generally conceded by astronomers that Lord Lindsay and Mr. Gill have rendered an important scientific service in this introduction of the most accurate of measuring instruments in the investigation of the sun's distance, by a method admitting of such repeated confirmation. Three of the minor planets approach the earth in the present year within the distance at which Juno was observed at the Mauritius in 1874.

THE SATELLITES OF MARS.—Prof. Asaph Hall, to whom, as the discoverer of these bodies, the right of selection of names appertains has definitively decided for *Deimus* for the outer moon and *Phobus* for the inner one, agreeably as he mentions to the suggestion of Mr. Madan in these columns, founded on the lines in the "Iliad," which Pope thus renders :—

"With that he gives command to *Fear* and *Flight*,
To join his rapid coursers for the fight;
Then grim in arms, with hasty vengeance flies,
Arms that reflect a radiance through the skies."

THE DATE OF EASTER.—Easter Sunday falling on April 21, is considered late this year, and it is thirteen days after the mean date, but it is to be remarked that in no year since the introduction of the Gregorian calendar into England has the festival occurred on the latest possible date, April 25, though in two years, 1761 and 1818, it fell on March 22, which is the other limit. In 1886, Easter Sunday will fall on April 25, in the new or Gregorian style, for the first time since the year 1734, or eighteen years before this style was accepted in England. The only other occasion since the reformation of the Calendar by Pope Gregory XIII., upon which Easter has fallen on the latest possible date was in 1666, and after 1886 this will not again occur till 1943.

BIOLOGICAL NOTES

THE AGRICULTURAL ANTS OF TEXAS.—Mr. H. C. McCook has presented to the Academy of Natural Sciences of Philadelphia a memoir on the habits of these most curious and interesting ants (*Myrmica molefaciens*, Buckley = *M. barbata*, Smith). An abstract of the memoir will be found in Sheet 20 of the *Proceedings* of the above Academy (p. 299). The author encamped in the midst of a large number of the ant hills during the summer of 1877, and carefully studied the habits of the inmates; the spot selected was in the neighbourhood of Austin, Texas, upon the tableland to the south-west of the Colorado River and its affluent, Barton Creek. The limestone rock here and there cropped up, the soil was black and tenacious, varying in depth from a few inches to three feet. The formicaries were very numerous, and were to be found along roads, in open fields, and in the very streets, paths, gardens, and yards of Austin; indeed, one was even seen in the stone-paved courtyard of an hotel. They are commonly flat circular clearings, hard and smooth; a few have low mounds in the centre, composed of bits of gravel of one or two grains' weight; the clearings vary in width from twelve to two or three feet. From each, roads three to seven in number, diverge into the surrounding herbage. These are often of great length, and during the working hours are thronged by the ants going and returning. The ants take their siesta during the meridian heat of the sun, generally stopping work about twelve, and not returning to it until two or three o'clock. The seeds collected were always taken from off the ground, they were chiefly seeds of small Euphorbiaceous and Rubiaceous plants, and of grasses. The ants proved to be true harvesters. The seeds were carried into the granaries through the central gates. They were shelled, and the hulls were carried out and deposited in refuse heaps, which, when carefully searched, yielded no perfect fruits. They seemed to be most fond of the grass called *Aristida stricta*, and it even seems possible that they sow this for themselves, though the author does not commit himself to this as a fact. The interior economy of the ant-hill is fully described. Here it may be noted that the ants are clever in attack, that their "sting" is as bad as a wasp's, and that they are so well versed in the science of war, that they would have been more than a match for Mr. McCook, had he not himself employed a small army (of two men) to fight with those ants that would fight with him while he was pulling their granaries, their nurseries, and their queen's palace to pieces, in order to let us know all about them. Prof. Leidy made some remarks on this paper, adding that he had studied the habits of an allied species (*M. occidentalis*) which he had met with during a summer in the Rocky Mountains. The habits of this species were very like those of the species described by Mr. McCook, but in addition Prof. Leidy mentioned that his species fostered a fine large Coccus for its saccharine production.

THE FIRST STAGES OF DEVELOPMENT IN PLANTS.—Great interest attaches to the earliest changes occurring after the fertilisation of the germinal cell or oösphere in plants; and the difficulty of the subject has taxed the ability of the best histological botanists. To satisfy the doctrine of evolution many students think it necessary to be able to trace homologies in the development of all stem-bearing plants. The latest investigation, which appears to carry the comparison further than has yet been attempted, is that of Mr. S. H. Vines, of Cambridge, who has diligently sought out and compared all the embryological evidence, derived from the writings of Hofmeister, Hanstein, Fleischer, Mettenius, Pringsheim, and many others. He shows that in all stem-bearing plants the germinal cell (that which is fertilised) divides into two portions, one of which gives rise to an embryonic tissue called suspensor, in higher forms, while the remainder alone produces the true embryo. This comparison is of especial interest in relation to mosses. In these plants it is the spore-capsule which is the product of the fertilisation of the germ-cell, and it is this capsule which corresponds to the whole leafy plant of a fern. Following out the analogy, the seta or stalk of the capsule in a moss corresponds with the part called "foot" in an embryo fern, and with the suspensor in flowering plants. Mr. Vines's paper is contained in the

January number of the *Quarterly Journal of Microscopical Science.*

RHIZOPODS IN AN APPLE TREE.—Freshwater rhizopods are beginning to be well known, but Prof. Leidy has lately discovered a number in an apple-tree. While waiting for a railway train, last December, his attention was attracted to a large-apple tree which had then quite recently been thrown down by a storm, and from the fork of its trunk he collected a small bunch of moss, which, on examining it carefully, he found to contain a number of rhizopods. Of these one was *Difflugia cassis;* it was abundant. Another, which occurred in smaller number, was *D. globularis,* and in addition, some specimens of *Trinema acinus, Euglypha alveolata,* and *E. brunnea,* were met with. The moss from which they were washed with filtered water was found at a distance of about eight feet from the ground (*Proceedings,* Acad. Nat. Scien. Philadelphia, 1877, p. 321). We hope this hint will not be lost by the investigators of our British or Irish rhizopods.

THE AERONAUTIC FLIGHT OF SPIDERS.—Many observations have been made on this singular phenomenon, but the Rev. H. C. McCook is pursuing his inquiries with a perseverance that succeeds in detecting many new details in the performance. Recently (October, 1877) he paid attention to groups of young wolf-spiders (Lycosidæ), which crowded the tops of railings in a meadow. Their faces were turned in the direction from which the wind was blowing; the abdomen in each was elevated at an angle of 45°, the claws brought in, and the legs stiffened, thus raising the body. From the spinnerets at the apex of the abdomen a single thread was exuded, and rapidly drawn out to several feet by the breeze. Gradually the foremost pair of legs sank to the level of the post, and the entire attitude became that of intense resistance. Then suddenly and simultaneously the eight claws were unloosed, and the spider mounted with a sharp bound into the air, and went careering across the meadow. As far as could be observed, it appeared that the spider took a voluntary leap at the moment of loosing its hold. One spider, by good hap, was followed through its flight. The position of the body was soon reversed, the head being turned in the same direction as the wind. The legs were spread out, and were united at the claws by delicate filaments of silk. After flying a distance of about eighty feet, the spider gradually settled down upon the meadow. The difficulty of this observation will be understood by entomologists, for it required exact suitability of position as to light, the limitation of the flight to a moderate height, and a comparative moderation of its speed. (*Proc.,* Acad. Nat. Sci. Philadelphia, 1877, p. 308.)

TURKOMAN GREYHOUNDS.—The Jardin d'Acclimatation has lately been enriched (we learn from *La Nature*) with three Turkoman greyhounds of great beauty, the first specimens imported into Europe. The animals are known in the country under the name of Tazi, and are employed in catching hares, like the Sloughi in Algeria and the greyhounds in Persia. They are of noble aspect, and have great strength of muscle; their head is remarkably long and delicate in form. The hair on the body is short; but the ears (which are very large) are covered with long silken hair. Their legs are also covered with well-developed hair, and the contrast of this with the upper smooth part of the body is surprising at first sight; the dogs appearing as if they had large waving pantaloons, or reminding one of some kinds of fowl. One of the three dogs was obtained from the Kirghises of Emba, the two others at Samarkand (and by M. de Ujfalvy). We believe that it is among this breed that, as mentioned by Hamilton Smith, the *stop* greyhound is found so trained, that when a whole pack of them is in pursuit of a doubling hare, a stick thrown before it instantly produces a general halt, and one only is then signalled out to pursue the game.

GEOGRAPHICAL NOTES

CHINA.—Mr. E. C. Baber's long-deferred Report on the journey of the Grosvenor Mission through Western Yünnan, from Tali-fu to Têng-yüeh, contains much matter which is of interest from more than one point of view. The most important of his surveys is that of the route from Tali-fu to Têng-yüeh, as it connects Garnier's explorations with the work of Sladen's expedition, and thus puts Bhamo in topographical communication with Shanghai and Saigon. The survey next, but not much inferior, in importance, is the route from Yünnan-fu to Tali-fu, in which the track followed was different to Garnier's. Mr. Baber has also prepared a running survey of his route across China from Hankow to Têng-yüeh. His remarks on the native races are interesting, especially in regard to the Kutung people. What or where Kutung is he was unable to ascertain; he describes the men as of a dark reddish complexion, with rather prominent features, above the average height and well-proportioned, dressed in close-fitting woollen garments, which in some cases were neatly cut and handsomely embroidered. The women seen would have been considered handsome anywhere; paler in colour than the men, their oval intelligent faces reminded the observer of the so-called Caucasian type, and in every step and movement there was a decision and exactness very different from the motion of a Chinese. One of the women, too, was particularly remarkable for a peculiarity of her long hair, which was naturally wavy, a feature never met with among the Chinese. Mr. Baber was fortunate in seeing the quarterly fair at Tali-fu, at which some 5,000 people were present, many of them being Lolos, Shans, Thibetans, &c. At this stage of his journey he propounds a not improbable explanation of the term "golden teeth," as applied to the inhabitants, viz., that it arose from the discoloration of the teeth produced by chewing betel with lime. Mr. Baber's observations on the extent of the poppy cultivation will hardly be found encouraging by those who desire to see the consumption of opium put an end to, for he says that his party walked some hundreds of miles through poppies; and a similar remark applies to his account of the trade-route into Yünnan from Burmah. The valleys, or rather abysses, he says, of the Salwen and Mekong must long remain insuperable difficulties, not to mention other obstacles between Yünnan-fu and Têng-yüeh. The members of Col. Sladen's expedition appear to have assumed that, when the latter place is reached, the obstacles to a highway into Yünnan have been surmounted, whereas the fact is that the difficulties begin at that place. Loth as most Englishmen are to admit it, Mr. Baber adds, the simple and evident approach to Eastern Yunnan is from the Gulf of Tonquin, but it by no means follows that the same holds true of the western part of the province. In conclusion we may mention that an interesting feature in Mr. Baber's report is his comparison of Marco Polo's narrative with his own experiences, and his verification in many respects of the Venetian's information respecting a country almost entirely unknown to Europeans.

PRJWALSKY'S JOURNEY TO LOB-NOR.—In the *Isvestia* of the Russian Geographical Society, and as Supplement 53 to Petermann's *Mittheilungen,* the narrative of Prjwalsky's journey from Kuldja to Lob-Nor and the Altyn-Dagh, is now published, with maps showing the route and the discoveries made. We have already referred to the results of this important journey between August, 1876, and July, 1877, a journey which the enthusiastic Dr. Petermann regards as the crown of Central Asiatic exploration, and as equal in importance to Stanley[illegible]urney down the Congo, or even the attainment of the Pole. Prjwalsky gives ample details as to what he saw along the route, and his observations will be of special value to the ethnologist as containing important details concerning the various peoples he met with. The zoologist and botanist will also find much to interest them. Not only does he bring certain information on the Lob-Nor, which is little better than a marsh, apparently drying up, but also makes an important contribution to our knowledge of the great mountain plateau which separates India from Central Asia. The Lob-Nor basin forms the foot of the Kuen-luen and of the great plateau which stretches from the plains of India over the Himalayas, the Karakorum, the highlands of Khor, in an unbroken sweep to the basin mentioned. Close by the Lob-Nor this mountain rises like a wall out of the low plain, some of the lowest valleys having a height of 10,000 feet above the sea. From this northern slope on the Lob-Nor, at about 60° W. long., the plateau stretches away south, for 13° (850 miles) to its southern slope on the Indian plain. At the meeting, on February 20, of the Russian Geographical Society the Secretary read a letter from Col. Prjwalsky, dated Fort Zaisan, January 11. The traveller said that, after having seen the impossibility of penetrating into Tibet *viâ* Lob-Nor, he was compelled to try the indirect route *viâ* Guchen and Hami, whence he proposed to go south to Tsandam and to Hlassa, crossing the sources of the Blue River. Thus, he left Kuldja on September 9, and reached Guchen. As along the whole of the route to Guchen, which passes through the towns Shikho and Manas, there were Chinese troops, as also many *champans* (convicts condemned to hard labour), Col. Prjwalsky followed another route, viz., to Lake Ebi-nor, thence north to the Saur Mountains, and thence to Guchen, along the route followed in 1875 by Col. Sosnovsky. Thus, he reached Guchen about the beginning of November, but here a serious illness compelled him to return to Zaisan, which he reached on January 13. A later telegram announced that the indefatigable traveller had recovered and that he was again on his way to Tibet.

MONGOLIA AND SIBERIA.—At the same meeting a letter from the traveller Potanin dated Bjisk, January 14, stating that he had arrived at the end of his Mongolian journey, after obtaining many hypsometrical and topographical data, as well as making rich botanical, zoological, and mineralogical collections. The Secretary of the Society gave a review of the activity of the Siberian department. Two expeditions were sent out by this department during the past year, one, which will be absent for several years, under the leadership of M. Czerski to investigate the shores of Lake Baikal geologically, the other conducted by M. Agapidin, to examine the flora of the district of Balagansk in the government of Irkutsk.

NEW GUINEA.—The Rev. S. Macfarlane has just sent home a report of a voyage which he made towards the close of last year from Murray Island to the east end of New Guinea, and in the course of which he visited several places previously unknown. He mentions having gone on shore near Killerton Point, not far from East Cape, where he found himself unable to communicate with the people except by signs, for they could not understand any of the dialects spoken at Teste Island, Port Moresby, and Murray Island, nor the Eastern and Western Polynesian languages, though upon inquiring the names of things, Mr. Macfarlane's companion thought he detected a resemblance to the Raratongan. The locality visited not suiting their purposes, the party went six or seven miles further to the eastward, and landed at the mouth of a river or mountain stream, where the hills slope down to within a short distance of the beach, and behind the village there is a well-wooded, fertile, and lovely valley. Mr. Macfarlane describes the neighbourhood as thickly populated, though the people are scattered in small villages within hailing distance of each other. Speaking generally, he says that the country about the east-end of New Guinea has a totally different appearance from that in the vicinity of Port Moresby, and the contrast was very striking. The former looked lovely and luxuriant, like the South Sea Islands, whilst the latter had a barren, brown, parched appearance, as if two days' sail had brought the party into a new country in quite a different latitude. We hear that Mr. Andrew Goldie, to whose gold discoveries in New Guinea we have before alluded, has sent home to the Earl of Glasgow an account of his recent explorations, accompanied by a sketch map and several drawings. At Mr. Goldie's request, his Lordship has handed the papers to the Geographical Society, and they will probably be read at one of the meetings during the present session.

LAKE NYASSA REGION.—A paper was read at Monday's meeting of the Royal Geographical Society, by Mr. H. B. Cotterill, "On the Nyassa, and a Journey from the North-East to Zanzibar." In August last he met Capt. Elton and some friends at the south end of the lake, and ran up the west coast. They were detained some days under Mount Chombi, which he ascended, and found to be about 4,000 feet above the lake. The high land on the west of the lake was found to trend off in a north-westerly direction. They at last made a start with about fifty men. Their route crossed the Chombaka River. The whole of the country was covered with groves of banana They procured other carriers and crossed the Chombaka Valley, crossing the river several times and passing two very beautiful little lakes. In crossing the Chombaka for the third time at a point where it flowed through a very deep ravine, they struck more towards the north. They found stretching away to the east and south-east a great plain bounded in the far distance by a towering range of mountains that evidently ran up from the eastern side of the Nyassa towards the north-west. The native name for these mountains and the surrounding country is Kondi. They had been gradually ascending since they left Nyassa, and when they reached Mazote's, they were at an elevation of about 6,000 feet above the sea. It was decided that some of them should push on to Mereri's Town. So Capt Elton and he and another started off, and having crossed the Kondi Range, they found themselves on a great plateau, 7,000 feet high, called Uwanji, a splendid cattle country, watered by many streams. Crossing the Makesumbi River, they found themselves in an undulating country, covered with thick bush. There Capt. Elton began to break down, and at South Ushekhe breathed his last. They then had to traverse some 350 miles of the Ujiji caravan route, and on the last day of February reached Zanzibar.

INDO-CHINA.—Dr. G. Barrion, a French naval surgeon is about to undertake an exploring journey to the Indo-Chinese peninsula.

MR. STANLEY has announced to the Paris Geographical Society that he will visit Paris in June, before his departure for America, to receive the medal the Society has awarded him.

NOTES

ROBERT JULIUS V. MAYER, whose name is so intimately associated with the mechanical theory of heat, died at his native town, Heilbronn, on the 21st inst., in his sixty-fourth year. We can only intimate the event this week, but hope next week to be able to speak in detail of Mayer's life and work.

IN connection with our article on Harvey in this number, we may remind our readers that for some time a movement has been on foot for the erection of a statue to Harvey in his native town, Folkestone. Only 800*l*., half the sum requisite, has been obtained, and we are sure many of our readers, on being made aware of the deficiency, will be glad to help to fill it up. Donations may be sent to the hon. treasurers of the fund, Sir George Burrows and Mr. Prescott Hewett, or to the hon. secretary, Mr. George Eastes, M.B., 69, Connaught Street, Hyde Park Square, W.

A great banquet, under the auspices of the College of Physicians, to be held on the day of the Harveian oration, is also talked of, but judging by the apathy shown generally on the subject of Harvey's tercentenary, it is not very probable it will come off. How is it that we take so little trouble here to keep alive the memory of our great dead?

We notice the death of Prof. A. Lamy at Paris on the 20th inst. For a number of years he has occupied the Chair of Industrial Chemistry at the École Centrale. As an investigator his name is chiefly known in connection with the metal thallium. Very shortly after the detection of its spectrum by Mr. Crookes in 1861, he observed the same phenomenon in the lead works at Lille; and his isolation of the metal and descriptions of its properties followed so closely on the announcements of the English chemist that the question of priority was vigorously discussed for some time, until finally decided against him. Contemporaneously with Mr. Crookes he submitted the new element to a careful examination, and it is to him we owe the first determination of the atomic weight 204, the discoveries of the poisonous properties, of the close relations with the alkaline group, of the remarkable thallium alcohols, and the preparation of thallium glass. In 1869 Lamy invented the two valuable pyrometers associated with his name, the one based on the dissociation-tension of calcium-carbonate for temperatures above 800°, and the second containing instead of carbonate the compound $CaCl_2,8NH_3$ for temperatures below 42°. In physics he studied the electric properties of sodium and potassium, and was the first to produce induction currents by means of terrestrial magnetism.

The death is announced of Michel-Charles Durieu de Maissonneuve, on February 20, aged eighty-two. He was honorary director of the Gardens of Bordeaux. As member of the Scientific Commission of Algeria he was known to botanists for his researches in the flora of that country.

We regret to announce the death of Prof. Gustav Willmanns of Strassburg University, well known through his African explorations and discoveries. Prof. Willmanns was only thirty-two years of age.

In the course of a few weeks a festival will be held in the city of Liége, to celebrate the fortieth year of the professorship of Theodore Schwann, the author of the cell-theory. To some of our readers it will be a startling piece of intelligence that the founder of modern histology is actually at this moment alive, and teaching as Professor of Physiology in the Belgian University. The committee charged with the management of the celebration desire the co-operation of scientific bodies and of individuals in this country. We are authorised to draw the attention of officials of the learned societies and other corporations to the approaching event, and to beg them to obtain some expression of sympathy with the object of the celebration—viz., the doing homage to the genius of Theodore Schwann. It is requested that letters intended to be read at the celebration may be forwarded either direct to the secretary, Prof. Edouard van Beneden, Liége, or to Mr. Ray Lankester, Exeter College, Oxford. All Englishmen of science who have specially occupied themselves in the field of work opened up by Schwann, are begged to communicate individually with either of the above-named gentlemen, and to forward their photographs for insertion in an album which is to be presented to the founder of the cell-theory.

M. Raoul Pictet, at Geneva, in consideration of the importance of his discoveries with regard to the liquefaction of gases, has had the honorary title of Doctor of Medicine conferred upon him by the University of Jena.

It was stated at the last meeting of the Royal Dublin Society that a new explosive agent has been discovered by Prof. Emerson Reynolds, in the Laboratory of Trinity College, Dublin. It is a mixture of 75 per cent. of chlorate of potassium with 25 per cent. of a body called sulphurea. It is a white powder, which is very easily prepared by the mixture of the materials in the above-named proportions. The new powder can be ignited at a rather lower temperature than ordinary gunpowder, while the effects it produces are even more remarkable than those caused by the usual mixture. Dr. Reynolds states that his powder leaves only 45 per cent. of solid residue, whereas common gunpowder leaves about 57 per cent. It had been used with success in small cannon, but its discoverer considered that its chief use would be for blasting, for shells, for torpedoes and for similar purposes. Dr. Reynolds pointed out that one of the advantages this powder possesses is that it can be produced at a moment's notice by a comparatively rough mixture of the materials, which can be stored and carried without risk so long as they are separate. The sulphurea, the chief component of the new explosive, was discovered by Dr. Reynolds about ten years ago, and could be easily procured in large quantities from a product of gas manufacture which is at present wasted.

The annual meeting in London of the Iron and Steel Institute commenced yesterday, and will be continued to-day and to-morrow. Discussions will take place on papers read at the Newcastle meeting, and several papers will be read on subjects of technical interest.

The great forge of Creusot has just despatched for an Italian ironclad two steel plates, weighing respectively 23,000 and 31,000 kilogrammes. They required a special railway train constructed for the purpose. The recent experiments at Spezia show that vessels protected by these plates are absolutely imperforable by any missiles so far known.

The rare phenomenon of St. Elmo's fire was observed at several localities in the Harz Mountains during the past month. At Blankenburg it occurred at a temperature of $+ 0^{\circ}{\cdot}5$ C. and pressure of 721·5 mm., after a series of storms. The air was so laden with electricity, that canes held aloft emitted from their points light blue flames five inches in length and three in breadth. In Döblitz the phenomenon occurred in the midst of a storm, half snow and half rain, when the ends of the branches in an entire grove were surmounted by flames from four to five inches in length.

A theory of the chemical action of light recently propounded by M. Chastaing is controverted by M. Vogel (in the reports of the German Chemical Society), who cites various facts to show that rays of any kind are capable of producing either an oxidising or a reducing action on inorganic substances, according to the nature of the substance by which they are absorbed; there is no ground for attributing to the less refrangible rays in all cases an oxidising, and to the more refrangible a reducing, power. M. Chastaing's second proposition, that light has an oxidising action on organic substances, which is strongest in the violet and weakest in the red, is also opposed by M. Vogel.

Cape Colony, New Guinea, the Australian Colonies, the South Seas, and, it would appear, almost every known portion of the southern hemisphere, have been suffering from a severe and protracted drought. Shade temperatures of 124° and 127° are reported from the interior of Australia, the heat being much less intense near the coast, owing to the strong sea-breezes which prevail in connection with the great heat of the interior. Sheep, cattle, horses, and the wild animals of these regions are dying off in thousands. In Cape Colony, in particular, complete ruin has overtaken large numbers of the settlers, many of the homes of hitherto well-to-do colonists having been broken up, and the several members gone into menial service in exchange for the barest necessaries of life. We have received several letters on this subject already, and shall be glad if our readers in the regions named will favour us with any information of which they may be in possession, suggesting or disproving the cyclical character of these droughts.

A PARIS correspondent sends us the following:—On March 15 a parricide was guillotined at Evreux (Eure), and a fraternity for burying the dead existing in the place, the body was not, as usual, thrown into a large basket and sent hurriedly to its grave. An ordinary coffin was prepared, and as soon as the execution was completed the corpse was laid in it. To the horror of the spectators the body was seen to be agitated by spasms so powerful that it almost jumped twice out of the coffin, and it was necessary to use force in order to control its motions. These contractions were, of course, unaccompanied by consciousness.

IN connection with the lamentable catastrophe to the *Eurydice* Sir George Airy sends to the *Daily News* some valuable information as to the meteorological condition on Sunday:—On Sunday, March 24, between 1h. 30m. and 3h. 0m., the wind, which had previously been almost imperceptible, had four times risen to a pressure of 1½ lb. per square foot; but from 3h. 0m. to about 3h. 55m. it was nearly calm, the pressure scarcely exceeding ¼ lb. per square foot. During the former of these two periods the direction of the wind had been fluctuating on both sides of west, but during the latter it was for the most part west-south-west. At 3h. 56m. nearly the direction changed very suddenly to north-north-west, and the force changed with most unusual suddenness to 4 lb., from which it rose at 4h. 3m. to 9 lb. per square foot. It declined for a time, but rose at 4h. 40m. to 10 lb. It fell and rose once more, and finally sank at 5h. 30m. to almost perfect calm. The fluctuations of the barometer were very inconsiderable. At 2h. 30m. it stood at 29·35 inches; at 3h. 56m. it was 29·28; and at 5h. 30m. was again 29·33. The temperature about 2h. 0m. had been as high as 49°, diminishing with fluctuations (probably produced by clouds) to 45° just before the squall. With the squall it sank most rapidly to 38°, and continued to fall, till at 5h. 0m. it was about 32°.

FROM an inquiry on the electromotive force and internal resistance of some thermopiles, those of Noe, and of Clamond, modified by Koch, M. Beetz concludes (*Ann. der Phys.*, No. 1) that the latter, from its great solidity, is preferable for technical purposes. That it requires to be heated long before use is of little consequence, and once in action, it works on with great constancy, both as regards electromotive force and resistance. Though, with an equal number of elements, the electromotive force is under that of the Noë pile, its utility is not less, as the elements can be easily increased. Only the burner must be improved in construction. On the other hand, the Noe pile offers the great advantage for laboratory purposes, that (by coupling several cylindrical piles) a productive current-source is readily obtained, with very constant electromotive force; the duration has been considerably improved in the new construction.

ACCORDING to *La Nature* the telephone is finding great favour in Spain; a goodly number are being produced in Barcelona, and numerous applications made of them. Telephonic chambers are being constructed designed to isolate the hearer from external noises and render communication more easy and sure. These chambers are of small size and have glass windows for light; the doors are closed with pads of caoutchouc. Telephony was lately tried between Barcelona and Saragossa, which are about 364 kilometres apart. The communication was satisfactory at the former place (notwithstanding bad weather); at Saragossa it was somewhat imperfect, which is accounted for by the telephonic chamber having been used at one place but not at the other.

As the latest instance of collections of personal contributions to scientific literature, we notice the appearance in Paris of a handsome volume containing Prof. Kuhlmann's various researches during the past half-century. The work affords not only an interesting glimpse into the lines of investigation followed out by a single mind, but also into the general progress of applied chemistry since 1830; for there is probably no chemist alive who has done more for the practical application of his science than this Lille professor. The present volume contains detailed accounts of the baryta industry, which he created, of the general introduction of crystallisation into technical operations, of the phenomena accompanying the use of cements and the formation of stone, as well as the minute studies on the formation of nitrates and artificial manures, on the crystallisation of insoluble bodies, on the madder dyes, as well as a great variety of other technical and purely scientific subjects. Prof. Kuhlmann is now in his seventy-fifth year, but is still able to contribute occasionally the results of new investigations.

UNDER the editorship of Heinrich and Gerhard Rohlfs, assisted by a numerous staff, Hirschfeld, of Leipzig, is publishing a new quarterly journal under the title *Deutches Archiv für Geschichte der Medizin und medizinische Geographie.*

THE French Academy has published the seventh edition of its "Dictionnaire de la Langue Française." Scientific terms have not been admitted into the general vocabulary except such as are now in common use and cannot be ignored even by unscientific persons.

MR. STAB, corresponding member of the Society of Arts, at Smyrna, reports that the plague of field-mice, or rats, has again broken loose, and that they are wasting the fields far and wide, digging up the seed-corn, and devouring all they can. This is the plague from which Homer records that Apollo Smynthius delivered the Greeks. As the Smynthian Apollo no longer has believers, Mr. Stab wishes to know what remedy can be recommended. The western states of America suffer much from this pest.

DR. A. B. MEYER, of the Royal Zoological Museum, Dresden, writes, in answer to Mr. Boulger's inquiry (vol. xvii. p. 392), that the reason why Mr. W. W. Wood did not send specimens of Navicula (NATURE, vol. xii. p. 514) is, that he died a short time after he wrote that letter. Dr. Meyer heard this from a Manila friend.

A BOTANICAL Exchange Society has been established at Buda-Pesth for the purpose of exchanging specimens of the native plants of Hungary, Transylvania, Croatia, Sclavonia, and, as far as possible, of Turkey and Russia, for those of other parts of the world. During the last two years upwards of 300 botanists have joined the Association, and more than 120,000 specimens have been distributed. All communications and applications for further information should be addressed to Herr Richter Lajos, Erzherzogin Marie Valerie Gasse, Nro. 1, Buda-Pesth, Hungary, accompanied by a subscription of 4 marks, or 5 francs, for which sum an exchange of 100 specimens will be effected.

A LECTURE will be delivered in the Theatre of the Royal Engineer Institute, Chatham, at five P.M., on April 3, by Prof. Huxley, F.R.S., on "The Geographical Distribution of Animals; and on Collecting and Observing in Aid of the Investigation of the Problems connected therewith."

ELECTRIC lights are becoming very common in Paris. The Lontain system is now working daily at the Lyons railway terminus at the expense of the Company. M. Jamin has published an elaborate article on the subject in the last number of the *Revue des Deux Mondes.*

THE telephonic signal invented by MM. Henry Brothers was exhibited at a lecture delivered at Montrouge under the auspices of the Paris municipal authorities. One apparatus was placed at the Mansion House and another at the Public School, at a distance of 500 metres. When each apparatus was used as a signal giver and connected with an ordinary telephone as receiver an air played at one end of the line could be heard by the whole audience at the other end. The Henry signal is constructed to work with a dry element, and requires no other wires than those of the telephone.

The *Midland Naturalist* continues to keep up the promise of its first number. No. 3, for March, has the first part of a lecture by Dr. Cobbold on the Parasites of Man, and among other interesting papers we may note those of Mr. Robert Garner on Edward Forbes and his Country, and the Ray and Palæontographical Societies: An Appeal, by Mr. W. R. Hughes.

Photographic Rays of Light is the somewhat unhandy title of a new photographic quarterly published in Baltimore, U.S.A. The contents are varied, and the journal seems likely to prove useful to photographers. The first number contains a photographic plate, "A Study in Artistic Photography."

In the February session of the Berlin Anthropologische Gesellschaft, Dr. Kahl-Rückhard delivered an elaborate address on the anthropology and ethnology of South Tyrol, a subject which has hitherto been untouched. This region has been swept over by so many tidal waves of invasion that the character of the original inhabitants has hitherto been entirely unknown. In order to solve the problem a large collection of skulls was obtained from an ancient charnel-house at Meran, and submitted to careful measurements. The results showed that they belonged to two sharply-defined classes. The first, a brachycephalic type, was evidently identical with that of the ancient Rhætians who formed the aboriginal population at the advent of the Teutonic tribes. The second variety, an orthocephalic type with dolichocephalic tendencies, cannot easily be classified. It is, however, certain that it does not coincide with the cranial type of the ancient Helvetians in the neighbouring parts of Switzerland.

At the workshops of the Michigan Central Railway at Jackson, Michigan, an interesting experiment was recently made, in order to ascertain the very shortest time in which a locomotive engine could be mounted ready for use from the finished component parts. Up to the present this work had been generally done by about five or six workmen in the space of from nine to fourteen days. When the fact became known that a Mr. Stewart of Jackson had done the work with fourteen workmen in twenty-five hours, and a Mr. Edington, with the same number of workmen, in 16½ hours, a bet between these two gentlemen was the result; and before a number of spectators they eventually both proceeded to mount a locomotive engine, each being assisted by fourteen workmen, and having all the parts of which the engine consists ready at hand. They accomplished the task in the remarkably short period of two hours and fifty-five minutes. The bet was won by Mr. Edington, who finished one minute sooner than his antagonist.

The additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus erythræus*) from India, presented by Mrs. Baxter; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mr. Jas. Bennett; a Malayan Bear (*Ursus malayanus*) from Malacca, presented by Mr. S. Palmer; a Short-toed Eagle (*Circaetus gallicus*), South European, presented by Mr. H. M. Upcher; a Savigny's Eagle Owl (*Bubo ascalaphus*) from Persia, presented by Dr. J. Huntly; two Reindeer (*Rangifer tarandus*) from Lapland, deposited; a Beccari's Cassowary (*Casuarius beccarii*) from South-East New Guinea, a Plantain Squirrel (*Sciurus plantani*) from Java, a Spotted Eagle Owl (*Bubo maculosus*) from South Africa, a One-streaked Hawk (*Melierax monogrammicus*) from West Africa, two Matamata Terrapins (*Chelys matamata*) from the Upper Amazons, an Anaconda (*Eunectes murinus*) from South America, received in exchange.

MIMICRY IN BIRDS

We have received two interesting contributions to this subject. One is contained in *The New Moon*, or Crichton Royal Institution Literary Register for November, 1873, being the observation on a starling by Dr. Crichton, the Medical Superintendent.

"Two or three years ago," he states, "in accordance with our principle of encouraging birds to become denizens of the grounds, we put up a few boxes for starlings. One of these was placed on the window sill of the writer's bedroom. Two years ago one of these birds took possession of the aforesaid box. Every morning, for two or three hours, he perched himself on an iron railing, erected to protect flowers, within two feet of the window, and there executed a comic medley with all the precision and effect of a finished *artiste*. The attention of the writer was first called to this extraordinary performance by having his window every morning surrounded by what appeared to be a general assembly of the whole tribe of *Aves*, wild and tame. The quacking of the duck, the screech of the lapwing, the eerie notes of the moorland plover, and many others, were imitated with a precision worthy of Mimos himself. He failed, however, to secure a mate for that year. Last year he was more successful. He revisited in spring his former cottage, and brought a mate with him. The usual family arrangements were made with the greatest care and despatch, when, in due time, a brood of young linguists made their appearance. During the hatching season our linguistic friend, every morning at dawn, resumed his perch within three feet of my bed, and for two or three hours, he repeated his extraordinary performance. The birds imitated always with the greatest precision are the hen, duck, goose, lapwing, plover, heron, and gull. The song or whistle of many small birds are also imitated. The only human note imitated is the whistle of the boy. This is frequently heard. It always begins on the same pitch, and passes downward through a major third, forming a beautiful musical curve. He is gradually adding to his vocabulary. During twelve months he has certainly added the cry of the heron, the gabble of the goose, and the cackle of the hen.

Mr. H. O. Forbes sends us the following instance:—

In the grounds of a friend in the neighbourhood of London, a colony of starlings had for many years built their nests in the trees in boxes placed here and there for their accommodation. The children of the house—all quite young then—a few years ago—at whose presence the birds showed not the slightest alarm, were constantly playing about close to the nests, and of course constantly calling each other by name. There was only one girl in the family, called *Maggie*, and as she was a great pet, perhaps her name was oftener mentioned than those of the others. Be that as it may, her father was one day greatly astonished by hearing his daughter's name pronounced in exact imitation of the voice of one of her brothers, whom he knew could not be near. For a moment he was puzzled, but close at hand, on the bough of an acacia tree, he detected the mocking-bird—a common starling—in the act of deception, which he continued to practice often afterwards.

AMERICAN SCIENCE

The comparison of the intensities of light of different colours has long been considered one of the most difficult of photometric problems. In the February number of the *American Journal of Science and Arts* Mr. Rood describes a simple method of making this comparison. The luminosity of cardboard painted with vermilion, *e.g.*, was determined thus:—A disc of the cardboard is attached to the axis of a rotation apparatus, and smaller discs of black and white (in sectors) are fixed on the same axis, so that by varying the relative proportions of black and white a series of grays can be produced at will. The compound black and white disc is first arranged to give a gray decidedly darker than the vermilion; this tint is now gradually lightened till the observer becomes doubtful as to the relative luminosities of the red and gray discs; the angle of the white sector is then measured. Next a gray decidedly *more* luminous than the vermilion is compared with it, and diminished in brightness till the observer again becomes doubtful, when a second measurement is taken. (The manipulation is done by an assistant without the experimenter knowing the exact black and white discs chosen.) From a number of such experiments a mean is obtained, which (it is proved) expresses the luminosity very correctly.

In an interesting paper on the glycogenic function of the liver Mr. Leconte, after stating that "the sole object of this function is to prepare food and waste tissue for final elimination by lungs and kidneys; to prepare an easily combustible fuel, liver-sugar, for the generation of vital force and vital heat by combustion, and at the same time a residuum suitable for elimination as urea," points out that the function is not *sugar-making*, as usually supposed, and which is a pure *chemical process* and *descensive* metamorphosis, but *glycogen-making*, *a vital function*, and *ascensive* metamorphosis. In diabetes the true organ *directly* in fault is not the kidneys nor the lungs, but the liver, which fails to arrest the sugar as glycogen. The starch-making function in plants offers a striking analogy to the function under consideration; for plants change soluble forms of amyloids (dextrin and sugar), into the insoluble form of starch (corresponding to glycogen, which is animal starch), and store it away for future use. This analogy is more remarkable in the lower animals and in embryonic conditions; the function often residing *in all parts* in such cases (as plants), while in higher animals it is confined to the liver. And it is sluggish animals that accumulate most glycogen in their tissues. Plants, however, store away the starch as building materials; animals, as fuel for force-making. Further attention is called to the close relation between the functions of the liver and kidneys. As we descend the animal scale, we find cases (*e.g.* insects) in which the same organ performs both functions. The fact of a large percentage of glycogen being found in the tissues of entozoa, which do not need any internal source of heat, is regarded by Mr. Leconte as a striking proof (if any were still needed) that the prime object of respiration is not *heat-making*, but *force-making*. Heat is only a concomitant, often useful, but sometimes useless, and even distressing.

Mr. Trouvelot, of Cambridge, furnishes accounts of three celestial phenomena observed by him, viz., undulations in the train of Coggia's comet, sudden extinction of the light of a solar protuberance, and the zodiacal light of the moon.

The atomic weight of antimony having been variously given by MM. Schneider, Dexter, and Dumas (using different methods), as 120·3, 122·3, and 122 severally, Mr. Josiah P. Cooke, jun., was led to a fresh study of the subject. The general conclusion which he reaches, after a very patient and laborious investigation (which the chemist will find highly instructive) is that the most probable value is $Sb = 120$ when $S = 32$.

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, March 7.—Dr. Gwyn Jeffreys, F.R.S., vice-president, in the chair.—Mr. Thos. Christy exhibited a series of fruits, among which were Chinese quinces, chayottes, and a remarkable citron known in China as the "claw of Buddha."—Prof. Ray Lankester also brought forward and made remarks on a collection of fossil walrus tusks (*Trichecodon Huxleyi* [?]) from the Suffolk crag, and sent him for examination by Mr. J. E. Taylor, of the Ipswich Museum.—Examples of a variety of *Helix virgata* were likewise shown by Mr. Rich.—On nudibranchiate mollusca from the eastern seas, by Dr. C. Collingwood, was the first paper read. He remarks that residents searching carefully within limited areas have more chance of obtaining new and interesting forms than have zoologists or extensively equipped expeditions who but pay hurried visits to tropical coasts. Season and other influences have much to do with abundance or paucity of species in given localities. He gives curious instances of specimens of nudibranchs, isolated in a dish of sea-water spontaneously and uncommonly neatly amputating the region of their own mouth. With other information the author further describes sixteen new species, illustrating the same with coloured drawings from nature. Mr. Thos. Meehan's paper, on the laws governing the production of seed in *Wistaria sinensis*, was communicated by the Rev. G. Henslow in the absence of the author. The latter alludes to the fact that the Wistaria, when supported, grows amazingly, but is seedless; on the contrary, the self-supporting so-called "tree-wistarias" produce seeds abundantly. These cases illustrate the difference between vegetative and reproductive force; they are not antagonistic, but supplement each other. While Wustaria flowers freely without seeding, it has been supposed this arises from the bees not cross-fertilising. Mr. Meehan submits data, however, in which he thinks the question lies rather in the harmonious relation between the two above nutritive powers than with insect pollenisation.—The Rev. M. J. Berkeley in an examination of the fungi collected during the Arctic Expedition 1875-76, mentions twenty-six species were obtained, all determined save two. Seven are new species, and seventeen already known widely distributed forms. The *Agaricus Feildeni* and *Urnula Hartii* are unusually interesting.—A paper on the development of *Filaria sanguinis hominis*, and on the mosquito considered as a nurse, by Dr. P. Manson, was read by Dr. Cobbold. Discussing general questions, he proceeds to show that the female mosquito, after gorging with human blood, repairs to stagnant water and semi-torpidly digests the blood. Eggs are deposited which float on the water and become the familiar "jumpers" of pools. The filariæ thus enter the human system along with the drinking water. Dr. Manson got a Chinaman whose blood was previously ascertained to abound with filariæ to sleep in a "mosquito house." In the morning the gorged insects were captured and duly examined under the microscope. A drop of blood from the mosquito was thus found to contain 120 filariæ, though a drop from a prick of the man's finger yielded only some thirty. The embryo once taken into the human body by fluid medium pierces the tissues of the alimentary canal. Development and fecundation proceed apace, and finally the filariæ met with in the human blood are discharged in successive and countless swarms, the genetic cycle being thus completed.—Dr. Cobbold, on his own behalf, further contributed a paper on the life history of *Filariæ bancrofti*, as explained by the discoveries of Wucherer, Lewis, Bancroft, Manson, Sonsino, and others.—Mr. Charles C. B. Hobkirk, of Huddersfield, was duly elected a Fellow of the Society.

Chemical Society, March 7.—Dr. Gilbert, vice-president, in the chair.—The following papers were read:—On some new derivatives of anisoil, by W. H. Perkin. The author has obtained orthovinylanisoil boiling 195°-200° C., sp. gr. at 15, 1·0095; orthoallylanisoil, boiling 222°-223° C. sp. gr. at 15, ·9972; and orthobutenylanisoil, boiling 232°-234° C. sp. gr. at 15, ·9817. The author compares the physical properties of the ortho- and para- compounds; the former boil about 10° lower, have a slightly higher specific gravity, and crystallise with much greater difficulty.—Note on the action of ammonia on anthrapurpurin, by W. H. Perkin. The author has investigated the colouring matters produced by the action of heat on an ammoniacal solution of anthrapurpurin in sealed tubes at 100° and 180° C. At the former temperature an unstable substance was obtained dyeing alumina mordants purple and weak, iron mordants indigo blue. At 180° a new substance, anthrapurpuramide, was formed, which does not dye mordants.—On certain polyiodides, by G. S. Johnson. The author attempted without success to prepare a compound having the composition $AgRI_6$, or a similar substance having thallium in place of silver; various compounds of silver and potassium, thallium and potassium, and especially a very complicated substance containing lead, acetic acid, potassium, and iodine were formed and analysed. The latter substance crystallises in square prisms; of the six phases two have a dark purple and four a greenish golden reflection.—On an improved form of wash-bottle, by T. Bayley. The object of this contrivance is to prevent the reflux of steam or other gases, such as ammonia, into the mouth of the operator, without losing the advantages of the ordinary wash-bottle.—On the preparation of glycollic acid, by R. T. Plimpton. The author endeavoured to prepare this substance by the method recommended by Prof. Church, but only obtained quantities too small for analysis, using two ounces of oxalic acid.

EDINBURGH

Royal Society, February 18.—Sir William Thomson in the chair.—Prof. Fleeming Jenkin read a paper on the application of the graphic method to the determination of the efficiency of a direct acting steam-engine. His results show that it is impossible to determine by empirical laws the efficiency of an engine as it varies with every change in the rate of action, the point at which the steam is cut off, &c.—Prof. Tait communicated a paper by Mr. Alexander Macfarlane, M.A., B.Sc., on the disruptive discharge of electricity. The difference of potential required to produce a spark between spheres for distances up to 15 centimetres is proportional to the square root of the distance between their centres and between parallel plates; it is a hyperbolic function of the distance between them; for a constant distance it is a similar function of the pressure of the gaseous medium for a range of pressures of from one atmosphere to 20 mm.—Mr. J. Y. Buchanan, of the *Challenger*, read a paper on the compressibilities of distilled water, sea-water, solution of chloride of sodium, and mercury. They were determined by instruments resembling piezometers immersed in the sea when free from currents, the approximate pressure being ascertained by the sounding-line. The compressibilities at various temperatures relative to that of distilled water were ascertained by compression in a powerful Bramah press. The compressibilities being found, these same instruments were used for measuring depths of the sea accurately when currents, &c., affected the indications of the sounding-line. A water piezometer was found to be much more sensitive to pressure than to temperature, a mercury one very sensitive to temperature and not so to pressure. The approximate depth was ascertained by the sounding-line, to which were attached the two piezometers. From the indications of the line and of the mercurial instrument the temperature of the bottom was approximately determined. This, applied to the indication of the water instrument, gave the depth accurately, and hence the true temperature was found from the mercurial. He described a new method of getting the compressibility of glass.—Prof. Crum Brown and Mr. A. Blaikie gave a paper on the decomposition of the salts of trimethyl sulphine by heat.—Sir Wm. Thomson communicated extracts from letters of Prof. Quincke, who has found that the surfaces of glass and quartz which have been for some time cut, change very much in their indices of refraction.—Prof. Jenkin mentioned some experiments by Mr. Gott on the telephone, which, he maintained, completely confirm Prof. Graham Bell's theory of the telephone.

Scottish Meteorological Society, February 1.—It was stated in the report from the Council that the Government had paid 1,000*l*. to the Society for past services rendered by it to a public department; that the Society has 102 regularly observing stations, in addition to the sixty lighthouse stations on the Scottish coast, and a large number of rain-observing stations; and that during the past four months seventy-five new members had been added to the Society.—Mr. Buchan read a paper on the weather of 1877, more special attention being given to the rainfall, the paper being illustrated by thirteen maps coloured according to the quantity of rain which fell in each month in different parts of the country. The maps represented in a strong light the influence of the physical configuration of the land on the rainfall in relation to different winds, both as regards their direction and their height in the atmosphere.

PARIS

Academy of Sciences, March 18.—M. Fizeau in the chair.—The following papers were read:—Motion of translation of cyclones; theory of a "rain motor," by M. Faye. He cites with satisfaction Prof. Loomis's recent conclusion from observations of the U.S. Signal Office, that "rainfall is not essential to the formation of areas of low barometer, and is not the principal cause of their formation or of their progressive motion"; and he regrets that the theory to which the "rain motor" belongs dies so hard.—On a trombe observed at sea, in December last, in the Straits of Malacca, by M. Faye. This was seen to descend from the clouds and penetrate the sea; the water rose round and exteriorly to the trombe.—M. Tisserand was elected member for the section of astronomy in place of the late M. Leverrier.—On the measurement of the mean density of the earth, by MM. Cornu and Baille. They have improved their apparatus by using four (instead of two) attracting spheres of mercury, and diminishing the distance of attraction. From an analysis of Baily's experiments, and with regard to resistance of the air, they show that the result was to assign too high a value for the mean density of the earth.—On the marine mollusca of Stewart Island (New Zealand), by M. Filhol. The number of these is 179.—Influence of rest and of motion on the phenomena of life, by M. Horvath. He placed in glass tubes a liquid favourable to multiplication of bacteria, and containing some alive. Some of the tubes were then continually agitated, while others, with the same quantity and at the same temperature, were left at rest. There was abundant multiplication in the latter, none in the former.—On interstitial fibromas of the uterus, by M. Abeille.—On improvements in the telephone, by M. Navez. He claims priority in use of the Ruhmkorff coil (which use, however, M. du Moncel carries back to Gray). For transmitter in Edison's system, he uses a battery of ten or twelve rundles of carbon. In the transmitter he uses a vibrating plate of copper covered with silver; in the receiver one of iron doubled on one of brass, and the two soldered together. Two magnets are employed in the receiver, with core and bobbin between, &c.—M. Vulpian presented M. Bernard's last volume, "Leçons sur les Phenomènes de la Vie commun aux Animaux et aux Végétaux, faites aux Muséum d'Histoir Naturelle."—Researches on absorption of ultra-violet rays b various substances, by M. Soret. *Inter alia*, distilled water, wit a thickness of 10 mm., is considerably less transparent tha quartz, and stops the last line of aluminium, but with greate thickness it takes the first rank, and it may be considered solvent of almost perfect transparence. Absorption in the ultra violet is subject to the same general laws as in the visibl spectrum. Several substances are mentioned which give absorption bands in the ultra-violet.—On a new telephone called th mercury telephone, by M. Breguet. This is on the principle of Lippmann electrometer. Suppose two vessels containing mercur with acidulated water above, and, dipping in the latter in eac a tube partly filled with mercury and ending below in a capillar point. The mercury in the two vessels is connected by wire likewise that in the two tubes. On speaking over one tube th air vibrations in it are communicated to the mercury, which translates them into variations of electromotive force, and thes variations generate corresponding vibrations in the air-mass o the receiver. The practical form of the instrument is an improvement on this.—On the daily oscillation of the barometer, by M. Renon.—Investigation of oxide of lead in the hyponitrate o bismuth of druggists, by M. Carnot. The hyponitrate is sometimes given to the extent of 10 to 20 grammes per day, and this might include one or two decigrammes of oxide o lead.—Researches on gallium, by M. Dupré.—Action of ozon on iodine, by M. Ogier.—Researches on suspension of phenomena of life in the embryo of the hen, by M. Dareste. An eg taken from a hatching apparatus after two days and replace after two days (the heart beats having quite stopped) develops chick as usual.—Proofs of the parasitic nature of anthrax; identit of lesions in the rabbit, the guinea-pig, and the sheep, by M. Toussaint.—On a new bioxide of manganese couple, by M. Gaiffe. This consists of a carbon cylinder with holes paralle to its axis filled with grains of bioxide of manganese; it is placed in a glass containing water and about 20 per cent. of chloride o zinc.—On three bolides observed in January and February a Damblain (Vosges) and Chaumont (Haute Marne), by M. Guyot.

THURSDAY, APRIL 4, 1878

THE SCOTTISH UNIVERSITIES COMMISSION

THE Report of the Royal Commissioners appointed to inquire into the Universities of Scotland, together with Evidence and Appendix, has just been issued. We will begin our reference to this important document with an extract (p. 49):—

> "It would, we consider, be a misfortune if the separate individuality which has long characterised the Scottish Universities were impaired, and if the spontaneous and healthy development of different schools of thought were rendered impossible by laying an obligation on men of original genius to make their teaching subservient in all its details to the requirements of an extraneous examining authority. The admirable influence which the Scottish Universities have hitherto exerted upon the people of the country has been due not only to the prolonged and systematic course of mental discipline to which their students have been subjected, but to the stimulus and encouragement given to inquiring minds by distinguished men who have made the professorial chairs centres of intellectual life; and we cannot think it desirable that any such changes should be made as would tend to lower the Universities into mere preparatory schools for some central examining board."

These words are peculiarly noteworthy at the present time, when attempts at centralisation are becoming more rampant than ever:—and when the general tendency of so-called "Educational Reform" is to substitute for teaching in the highest sense, an almost Chinese system of examinations, with their inevitable attendant *Cram*. For the true definition of Cram is "preparation for examination, and for examination alone":—and its varieties are infinite, ranging as they do from processes closely resembling the manufacture of *foie gras* in the live bird, to those which are adopted in dressing diseased meat for the market. The Scottish Universities have, it seems, been hitherto singularly free from this monstrous evil; and, it is to be hoped, will remain so The Commissioners who are now dealing with our great English Universities would do well to pay particular attention to this point, for Cram, in its worst forms, is by no means a stranger to them. The true cure for this evil is very well stated in the Report (p. 49):—

> "The examination of the students of a University for their degrees by the Professors who have taught them is sometimes spoken of as an obvious mistake, if not abuse; but those who are practically acquainted with University work will probably agree with us that the converse proposition is nearer the truth. In fact, it is hard to conceive that an examination in any of the higher and more extensive departments of literature or science can be conducted with fairness to the student, unless the examiners are guided by that intimate acquaintance with the extent and the method of the teaching to which the learner has had access, which is possessed only by the teachers themselves."

Nothing could be more true, or more happily put. Let all University instruction (in England as well as in Scotland) be real *teaching*, such as is (or at least ought to be) given by Professors or Lecturers and their specially chosen Assistants, and let the teachers be in the main the examiners. Mere speed of writing, and other similar qualifications, are unworthy the notice of scientific men or scholars—and certainly ought to have no influence in a University Examination, at least until Universities are furnished with Professors of Caligraphy, Maintien, &c., attendance upon whose lectures shall be made compulsory. It is right and proper that such things should be looked to in Civil Service Examinations and the like- just as it is right that the candidates in some of these should be submitted to medical inspection. But who ever heard of medical inspection in a University examination?

But we now come to the one true difficulty in this part of the question:—*How to choose Professors*. On this point there are several very useful hints, both in the *Report* itself and in the *Evidence* appended.[1] The Commissioners do not seem very decided in their recommendations, so many widely differing and yet individually plausible schemes have been submitted to them. But practically the patronage seems from the evidence to be very fairly bestowed (*i.e.*, in very good hands) in the majority of the Scottish Universities. The main exception is that of Edinburgh, where several of the most important chairs were left by the Universities (Scotland) Act, 1858, virtually in the gift of the Town Council, which had been up to that date the supreme authority in the metropolitan University. Such a state of things is barely credible to us in England. For, though custom has familiarised us with great schools under the management of City Companies, we could hardly imagine the Mayor and Aldermen of Cambridge electing to the Lowndean or Lucasian Professorship. Yet the chairs once held by Maclaurin, Black, Leslie, Dugald Stewart, &c., are at the disposal of a Board of seven, four of whom are nominated by the Edinburgh Town Council! Instead of the heroic treatment which such malformation demands, and which would probably have made opposition impossible; the Commissioners propose merely to create two additional members of this Board, so as to place the Town Council representatives in a minority; a step whose timidity may only ensure a violent, and too probably a successful, resistance.

It appears clearly from these volumes that the one great want of the Scottish Universities is *money*. Over and over again, throughout the evidence, this is painfully brought out. Yet, with their few thousands these Universities are at present educating many more students than Oxford and Cambridge together, each of them with its annual hundreds of thousands. And the education given to each and all is generally of the highest order, because it is given by the Professors themselves. How many Cambridge men go for instruction to Cayley or Stokes—to Munro or Kennedy? Of names like these Cambridge is justly proud. But unfortunately such teaching as these men could give *doesn't pay*, so the "coach" is resorted to! In Scotland the Professors are the teachers, hourly accessible to all, and among the latest additions to their ranks we find the names of Jebb and Chrystal. They will do more good to students now in one year than they could have done in a lifetime spent in Cambridge! Comment on such a statement is needless.

After what we have just said, the reader will scarcely be prepared to hear that one great reproach to the Scottish University system is commonly thought to lie in the shortness of the session, as it is called. This is a great point with would-be University reformers—"Go to, ye are idle." But it will be found, on examination, that the compulsory working-time *per annum* is longer at the Scottish than at the English Universities:—whence men go down regularly whenever term divides. In Scotland the majority of the lectures continue uninterrupted (except by the week from Christmas to New Year) from the end of October to the middle of April; and by that time both students and professors *require* some relaxation, especially those who have to teach or attend the summer classes, which occupy the whole of the months of May, June, and July. The Commissioners have no hesitation on these points, and meet the grumblers very sharply. They say:—

---

[1] The Analysis or Abstract of the Evidence, which is contained along with the Report itself in the first of these four Volumes, seems to be exceedingly well executed throughout. This is one of the specially good features of the work, and Prof. Berry, the Secretary to the Commission, deserves high credit for it.

"Without saying that the present arrangement of the academical year is the best that could be devised, it is that which long experience has shown to be the most suitable to the circumstances of Scotland. Nor is it without its advantages for the purposes of study. To the well-advanced and intelligent the vacation affords an opportunity for reflection and self-culture, so as to prevent his University education from degenerating into a mere acceptance of facts and conclusions from the mouth of his teacher. For a student, indeed, who is backward or indolent, the leisure afforded by the long vacation may be useless and hurtful. But to meet the case of such students the fitting remedy is that which we have already stated, the institution of summer tutorial classes where these do not now exist, and their extension, if necessary, where they do."

Our readers are already acquainted with the Report of the Devonshire Commission. A good deal of the evidence which that body collected has been taken as repeated before the present Commissioners, and they adopt, and strongly urge the carrying out of, several of the recommendations of their predecessors:—especially those which concern grants of public money for the extension of buildings and appliances for Science teaching in the Scottish Universities. It is well that this has been done, for attention has thus been recalled to one of the most important documents connected with education which has ever been laid before Parliament, and which (probably because of the moneys it recommended to be granted) has been practically shelved for some years.

So far we have been dealing with the Report as a whole. We must now more particularly examine it as regards *Science*. And this, we fancy, will be allowed to be its weakest point. The Commission was exceedingly strong on the literary, legal, and general-culture side:—but very weak—numerically at least—on the scientific. It is no disparagement to such men as Dr. Lyon Playfair and Prof. Huxley (who were the *two* representatives of Science among *twelve* Commissioners) to say that they cannot adequately represent *all* science. For there are three great divisions of Science, the Observational, the Experimental, and the Mathematical, and the third and greatest of these was altogether unrepresented on the Commission. This was a very grave defect, and the value of the Report is considerably reduced in consequence.

So strong, in fact overwhelming, was the general culture side—including Members (or ex-Members) of both Houses of Parliament, Scottish (and Indian) Judges and Advocates, &c.—that the Report cannot fail to surprise all readers by its general tenor. For there can be no question that in it Science has managed to carry the day against all comers:—the greater the pity that it was not fully represented, if but by the addition of a single mathematician. To make room for him, a lawyer might easily have been spared.

We cannot spare space for more than one instance of the proposed revolution:—but we choose an important and typical one, the modifications to be made in the mode of attaining the degree of M.A. This degree has hitherto, in Scotland, involved a certain amount of knowledge of *each* of the following seven subjects:—Latin, Greek, Mathematics, Logic, English Literature, and Moral and Natural Philosophy:—and has not been at all nearly so easy to attain as the ordinary (or Poll) degree in the English Universities—which, though at first styled only B.A., becomes M.A. by mere lapse of time and payment of additional fees, and is therefore practically the same thing. In Scotland it is now proposed that there shall be five distinct avenues (several with alternative branches) to this degree in addition to the present one:— (p. 25)

"Moved by these considerations, we have come to the conclusion that to secure a basis of general culture every student proposing to proceed to the degree of M.A. should be required to pass a 'First Examination' in Latin, Greek, Mathematics, English, and, when the state of education in the schools renders it practicable, in Elementary, Physical and Natural, Science. This examination should be passed at the beginning of the University session,—either the winter or the summer session,—every student proposing to graduate being required to pass it, whether he may have been previously a student in the University or not. With some modification, the examination might be so adapted as to apply not only to students proceeding to a degree in Arts, but to those also intending to graduate in Law, Science, or Medicine. In the case of persons proceeding in Law, we think that an examination in translating from French or German should be allowed as an option for Greek. Again, in the case of students proposing to graduate in Science or Medicine, we think that, as some knowledge of modern languages is most important to them, they should be examined either in translating from French and German, or in translating from one of the languages and in Greek. In this way, it would be necessary for them to show ability to translate from at least one modern language.

"As we shall explain afterwards, we regard this as the best equivalent for an entrance examination. Through its application to all proposing to graduate, whether previously students at the University or having come direct from school, a salutary reflex action on the schools will be secured by the encouragement given to them to send their pupils to the University in an advanced state of preparation. In a different shape, and if accompanied by the condition of exclusion from the University should the candidate fail to pass, an entrance examination would, in our opinion, be attended with injury rather than benefit.

"After passing the 'First Examination,' the candidate for a degree in Arts should be allowed to proceed in the present course, if he please, and as, no doubt, many will still do. If, however, he prefer to take a different course, we propose that he should be allowed to take any one of the five following departments or lines of study, viz.:—

"I. Literature and Philology.
II. Philosophy.
III. Law and History.
IV. Mathematical Science.
V. Natural Science.

'The branches to be included under these different departments we propose should be as follows :—

"I. Literature and Philology should comprise the subjects of Latin ; Greek ; and English Literature ; together with one of the following subjects, viz. : Comparative Philology ; Sanskrit ; Hebrew ; a Modern Language ; Gaelic, with Celtic Philology. Questions on history and geography incidental to each subject should form part of the examination.

"II. Philosophy should include Logic and Metaphysics ; Ethics and Psychology ; and the Physiology of the Nervous System. The first two subjects are understood to embrace the History of Philosophy.

"III. Law and History should include Civil Law ; either Constitutional Law or International Law ; and Political Economy ; together with the history of any one of the following groups, viz. : Greece and Rome ; Modern Europe ; Egypt, Syria, Palestine, and Arabia ; India ; Ancient and Modern America.

"IV. Mathematical Science should embrace Mathematics, pure and applied ; Natural Philosophy ; and Physical Astronomy.

"V. Natural Science should comprehend four groups, viz. :—(1) Applied Mathematics, Natural Philosophy, and Chemistry ; (2) Natural Philosophy, Chemistry and Physiology ; (3) Physiology, Botany, and Zoology ; (4) Natural Philosophy, Chemistry, and Geology. A candidate should be allowed to take any two of these four groups ; and the practical working of the arrangement would be that Natural Philosophy and Chemistry would be compulsory, while any option would be given between the mathematical and the morphological sciences.

"It may be explained that the subjects of examination in the sciences comprehended in Department V. are such as are required in the first Bachelor of Science examination as detailed in the Calendars of the Universities of Edinburgh and London (1877). The purpose we have had in subdividing the subjects of Department V. into groups has been, in the first place, to ensure a sound acquaintance with Physics and Chemistry, which lie at the foundation of all natural science ; and, in the second place, so much being secured, to give fair play to individual intellectual tastes and peculiarities. It is rare to find a man equally capable of dealing with long chains of abstract reasoning, or with experimental research, and of observing and remembering the analogies and differences of form. The scientific aptitude, when strongly marked, is either for mathematics, for experimental investigation, or for morphology, rarely for all three.

"In regard to the scientific subjects, mere book knowledge should not suffice ; practical work in the laboratory should be essential."

We are much mistaken if this Report does not produce great irritation, amounting in many quarters to white heat at least, and determined opposition. The dry husks of speculative "philosophy" which, feebly existent even in the present day (like Bunyan's *Pope* and *Pagan*), formed so large an ingredient in the mental pabulum of Scottish students in the past, are doomed to "cease from troubling" :—but they will die hard. In their place will come the still oppressed truths of modern science, and the legitimate speculations which Experience and mathematical power alone can enable the human mind to originate and develop.

SUN-SPOTS AND RAINFALL

THE paper which we print from Mr. Meldrum this week, appearing as it does within a few days of the debate in the House of Commons on the Indian Famine expenditure, is one which should be interesting to many besides professed meteorologists. It will, for one thing, enable even the most unscientific among us to see the manner in which men of science are striving to arrive at the truths of nature the while the average Member of Parliament only refers to their labours in order to sneer at them even when their results may elucidate a question of high national importance.

Granting that the Member for Cambridge comes up to the average of our legislators, let us see how he distinguished himself on Tuesday. In his indictment of the policy of Sir John Strachey, he was unwise enough to touch on the question of the connection between sun-spots and the Indian rainfall. "It appeared that, according to the astronomer to the government at Madras, the absence of several important spots (*sic*) on the sun's disc was connected with the retarded rainfall." It is clear from this, we think, that Mr. Smollett, in his ignorance of all things solar, instead of taking a little trouble to inform himself, has built up a mental image of the physics of our central luminary, by likening it to the house of which we will grant again he is one of the most prominent units. The cause of the sun-spot minimum appears to him to be that at this time "several important spots"—let us say the Smolletts of the sun—are in the tea-room or at dinner, anyhow they are absent from the division, and the opposition carries the day—that is, if Mr. Pogson is right, but he proceeds to show that Mr. Pogson is wrong.

Dr. Lyon Playfair, as was to be expected, put this matter right before the house. He stated that "it was established that famines in India came at periods when sun-spots were not visible. Out of twenty-two great observatories of the world it had been shown in eighteen that the minimum rainfall was at times when there were no spots on the sun. That was as true in Edinburgh as in Madras, in St. Petersburg as in Australia. It was therefore essential for the Government of India to take that into consideration in calculating as to when famines were likely to occur. The Secretary of State for India had acted wisely in sending out photographers to the Himalayas to take photographs of the sun, and having seen some of those, he was sorry to say that on none which he had seen were spots to be detected." As Dr. Playfair is not in the habit of making statements without getting up his case, we may be thankful to Mr. Smollett for the sneer which called Dr. Playfair up.

Mr. Meldrum's communication contains a very condensed reference to his memoir on Sun-spots and Rainfall recently presented by him to the Meteorological Society of the Mauritius, a memoir which goes far to complete one portion of that magnificent edifice, the erection of which was foreseen by Sir Wm. Herschel at the beginning of the present century.

In this important paper Mr. Meldrum, than whom there exists no higher authority, states that the result of his seven years' work has been to convince him that the connection between sun-spots and rainfall is as intimate as that between sun-spots and terrestrial magnetism ; and that having regard to the number of cycles at our disposal we should be as justified in rejecting the diurnal oscillation of the barometer as the curve along the hills and hollows of which the maximum and minimum rainfalls of the world lie.

This result of course will be received with incredulity by many—and for many reasons. In the first place the enormous variation in the solar activity is a fact only fully realised by very few. Men grown old in the service of science are as a rule as little anxious to receive new ideas as men grown old in any other of the world's activities, and further and more than this, in the case of many there is what has recently been happily termed "a paralysis of the imagination"—a thing far removed from scientific caution—which may and indeed certainly would do much harm to scientific progress if those afflicted with it had any chance of having the exclusive say in the matter.

Now that things have arrived at this stage it is well to bring to the front some extracts from those papers of Sir Wm. Herschel's to which reference has already been made, to show the wonderful prescience of the man, and also to give an idea of the valuable time which has been lost by the neglect, during three-quarters of a century, to take in hand the work from which he predicted such a rich harvest of benefits would follow.

His first reference to the *changes* going on in the sun was made in 1801.[1] He writes:—

"On a former occasion I have shown that we have great reason to look upon the sun as a most magnificent habitable globe; and, from the observations which will be related in this paper, it will now be seen that all arguments we have used before are not only confirmed, but that we are encouraged to go a considerable step further in the investigation of the physical and planetary construction of the sun. The influence of this eminent body on the globe we inhabit is so great and so widely diffused that it becomes almost a duty for us to study the operations which are carried on upon the solar surface. Since light and heat are so essential to our well-being, it must certainly be right of us to look into the source from whence they are derived, in order to see whether some material advantage may not be drawn from a thorough acquaintance with the causes from which they originate.

"A similar motive engaged the Egyptians formerly to study and watch the motions of the Nile and to construct instruments for measuring its rise with accuracy. They knew very well that it was not in their power to add one single inch to the flowing waters of that wonderful river; and so, in the case of the sun's influence, we are likewise fully aware that we shall never be able to occasion the least alteration in the operations which are carried on in the solar atmosphere. But if the Egyptians could avail themselves of the indications of a good Nilometer, what should hinder us from drawing as profitable consequences from solar observations? We are not only in possession of photometers and thermometers, by which we can measure from time to time the light and heat actually received from the sun, but have more especially telescopes, that may lead us to a discovery of the causes which dispose the sun to emit more or less copiously the rays which occasion either of them; and if we should even fail in this respect, we may at least succeed in becoming acquainted with certain symptoms or indications, from which some judgment might be formed of the temperature of the seasons we are likely to have.

"Perhaps our confidence in solar observations made with this view, might not exceed that which we now place on the indications of a good barometer with regard to rain or fair weather; but even then a probability of a hot summer, or its contrary, would always be of greater consequence than the expectation of a few fair or rainy days.

"It will be easily perceived that in order to obtain such an intimate knowledge of the sun as that which is required for the purpose here pointed out, a true information must be first procured of all the phenomena which usually appear on its surface."

He then gives those wonderful observations which make this paper the basis of our knowledge of the smaller units of the sun's surface, and then sums up as follows:—

"From these two last sets of observations, one of which establishes the scarcity of the luminous clouds, while the other shows their great abundance, *I think we may reasonably conclude that there must be a manifest difference in the emission of light and heat from the sun.* It appears to me, if I may be permitted the metaphor, that our sun has for some time past been labouring under an indisposition, from which it is now on a fair way of recovering.

"An application of the foregoing method, however, even if we were perfectly assured of its being well founded, will still remain attended with considerable difficulties. We see how, in that simple instrument the barometer, our expectations of rain and fair weather are only to be had by a consideration of many circumstances besides its actual elevation at the moment of inspection. The tides also present us with the most complicated varieties in their greatest elevation, as well as in the time when they happen on the coasts of different parts of the globe. The simplicity of their cause, the solar and lunar attractions we might have expected, would have precluded every extraordinary and seemingly discordant results.

"In a much higher degree may *the influence of more or less light from the sun be liable to produce a great variety in the severity or mildness of the seasons of different climates and under different local circumstances*, yet when many things which are already known to affect the temperature of different countries and others which future attention may still discover, come to be properly combined with the results we propose to draw from solar observations, we may possibly find this subject less intricate than we might apprehend on a first view of it.

"If for instance we should have a warm summer in this country when phenomena observed in the sun indicate the expectation of it, I should by no means consider it as an unsurmountable objection, if it were shown that in another country the weather had not been so favourable.

"And if it were generally found that our prognostication from solar observations held good in any one given place I should be ready to say that with proper modifications they would equally succeed in every other situation.

"Before we can generalise the influence of a certain cause we ought to confine our experiment to one permanent situation, where local circumstances may be supposed to act nearly alike at all times which will remove a number of difficulties."

This was in April; in May he read another paper.[1]

"Having brought the solar observations relating to the symptoms of copious emission of the light and heat of the sun to the 2nd of March I gave them continued in this paper to the 3rd of May. It will be seen that my expectations of the continuance of the symptoms which I supposed favourable to such emissions, have hitherto been sufficiently verified; and by comparing the phenomena I have reported with the corresponding mildness of the season, my arguments will receive a considerable support.

"I have given the following observations without delay as containing an outline of the method we ought to pursue in order to establish the principles which have been pointed out in my former paper. But we need not in future be at a loss how to come at the truth of the current temperature of this climate as the thermometrical observations which are now regularly published in the *Philosophical Transactions* can furnish us with a proper standard with which the solar phenomena may be compared. This leads me to remark that although I have in my first paper sufficiently noticed the want of proper criterion for ascertaining the temperature of the early periods where the sun has been recorded to have been without spots, *and have also referred to future observations for showing whether a due distribution of dry and wet weather with other circumstances which are known to favour the vegetation of corn, do or do not require a certain regular emission of the solar beams*, yet I might still have added that the actual object we have in view is perfectly independent of the result of any observations that may hereafter be made on the *favourable or defective vegetation of grain in this or in any other climate* . . . . It may be hoped that some advantage may be derived even in agricultural economy, from an improved knowledge of the nature of the sun and of the causes or symptoms of its emitting light or heat more or less copiously."

---

[1] "Observations tending to investigate the Nature of the Sun in order to find the Causes or Symptoms of its Variable Emission of Light and Heat; with Remarks on the Use that may possibly be drawn from Solar Observations." By William Herschel, LL.D., F.R.S., read April 16, 1801.

[1] "Additional Observations tending to Investigate the Symptoms of the Variable Emissions of the Light and Heat of the Sun; with Trials to set aside darkening Glasses by Transmitting the Solar Rays through Liquids, and a few Remarks to Remove Objections that might be made against some of the Arguments contained in the former Paper," by William Herschel LL.D., F.R.S. Read May 14, 1801.

It perhaps will be news to many that the idea of a possible connecttion between sun-spots and rainfall which has been represented as a modern idea, may really be credited to a man whose chief work was done in the last century.

DARWIN'S "DIFFERENT FORMS OF FLOWERS"

The Different Forms of Flowers on Plants of the same Species. By Charles Darwin, M.A., F.R.S. (London: John Murray, 1877.)

THIS is another of the remarkable series of volumes in which Mr. Darwin has given us the extremely valuable results of his researches in the vegetable side of biology. Mr. Darwin's method of investigation would in itself be a very interesting subject for consideration. It is, however, sufficient to point out that its characteristic feature is the combined attack upon a given problem from both its morphological and physiological aspects. This method Mr. Darwin employs with consummate success, and in turning over the pages of the present book—a considerable part of which has been before the world for more than a decade without being materially impugned—one is almost distracted from the intrinsic interest of the facts and speculations by the sagacity with which the research is carried on, and the skill with which the results are marshalled for our information. It is peculiarly worthy of notice in the present volume how the reader is allowed, in studying Mr. Darwin's pages, to form his own hypotheses in explanation of the facts, only to be compelled in due course, as the narrative proceeds, to admit that such hypotheses are utterly untenable. There is no impression so curious as to find oneself so distinctly under the hands of a master, and to realise that the calm flow of the argument proceeds over the *débris* of objections and difficulties which are found to be already comminuted as soon as one attempts to give them any definite form.

It would be quite impossible to treat, in the short space at our disposal, all that calls for notice in the present volume. Commencing with a short introduction, the body of the book falls into three divisions. The first treats of heterostyled plants, and contains in a connected form the substance of Mr. Darwin's various papers communicated to the Linnean Society. The second and third divisions are much shorter, and treat respectively of the passage of hermaphrodite into diœcious plants, and of cleistogamic flowers.

As has been already remarked, Mr. Darwin's researches on what are now termed heterostyled plants have been common scientific property for many years, and have filtered down into the current text-books. The seventh and eighth chapters are therefore the essentially new part of the book, and these we shall more particularly consider.

The vast majority of flowering plants are, as is well known, hermaphrodite, that is to say, they contain within the same floral envelopes both male and female organs. The governing principle in the morphological adaptations of flowers is apparently to escape the obvious consequences of such juxtaposition and evade self-fertilisation. This is effected either by their being dichogamic—that is the sexual organs in any one flower maturing at different times, or by their being entomophilous—that is calling in the intervention of insects to carry the pollen of one flower to the stigma of another, or by their being heterostyled—that is by the flower being modified in two or three ways, admitting of a certain number of reciprocal modes of fertilisation which are legitimate, and of others which are distinguished as illegitimate, and are more or less sterile.

Each of these modes of avoiding self-fertilisation practically sets up a functional separation of the sexes, and it might seem that the cases in which this separation is *structurally* accomplished are its natural sequence. Mr. Darwin points out, however, very conclusively that this is by no means the case.

> "There is much difficulty in understanding why hermaphrodite plants should ever have been rendered diœcious. There would be no such conversion unless pollen was already carried regularly by insects or by the wind from one individual to the other, for otherwise every step towards diœciousness would lead towards sterility. As we must assume that cross-fertilisation was assured before an hermaphrodite could be changed into a diœcious plant, we may conclude that the conversion has not been effected for the sake of gaining the great benefits which follow from cross-fertilisation."

Mr. Darwin is led to find an explanation in the advantage to the plant in the diminished strain of producing sexual organs of only one kind instead of both. And the process of manufacturing diœcious plants is one which can be actually seen in process. The cultivated strawberry under the influence of the American climate is a marked instance. In such cases the hermaphrodite state can be traced into the diœcious with every intermediate grade. The ultimate fate of heterostyled plants is perhaps to be converted into diœcious ones, and in this instance the change would be more immediate and with fewer connecting links. The functional diversity already exists and the corresponding suppression of the sexual organs is all that is needed to render it complete.

The concluding chapter on cleistogamic flowers certainly does not yield in interest to any preceding portion of the book. The existence of these curiously-modified structures has long been known, but it is only within the last twenty years that they have been attentively studied, and Mr. Darwin's account is a very masterly discussion of all that has been written on a very puzzling subject, tested and enriched by his own observations and experiments. As their name implies, these flowers never open, and in some cases they have been passed over as abortive bud-conditions of flowers of the normal conspicuous type. Their petals are, of course, superfluous, and are usually completely suppressed, or nearly so, the stamens and pistil are also much reduced in size, but though morphologically reduced, are physiologically fully developed, and such flowers are very fertile. In fact, in some instances, as in *Viola canina*, the production of seed is principally dependent upon them, the ordinary flowers, from want of pollen, or the absence of the visits of bees, rarely producing capsules.

At first sight the suggestion seems a tempting one, that in these curiously degraded flowers, in which all the laboriously-acquired adaptations for cross-fertilisation are entirely discarded, we have a reversion to a less highly organised ancestral type. And this may still to some extent be true, though Mr. Darwin shows that they "owe their structure primarily to the arrested development of perfect ones." In some cases, as Oliver has shown in *Campanula colorata*, and Scott in *Eranthemum ambiguum*, the same plant bears as well as cleistogamic and perfect flowers, intermediate forms between the two. What is, however, still more significant, is that the cleistogamic flowers are themselves sometimes the starting point of structural adaptations, to effect more perfectly the self-fertilisation which ordinary flowers have been so marvellously modified to avoid. Thus, in *Specularia perfoliata* the rudimentary corolla is modified into a perfectly closed tympanum, and in *Viola canina* the pistil is much modified. Mr. Darwin, however, has shown that cleistogamic flowers do not invalidate the general principle as to the disadvantage in the long run of self-fertilisation. After two years' growth, crossed seedlings of *Ononis minutissima* beat those produced from cleistogamic flowers in mean height in the ratio of 100 to 88.

It seems that the end really gained by cleistogamic flowers is the production of a large supply of seeds with little expenditure; the plant does the work more cheaply and makes the numbers pay. It is curious to reflect what, relatively speaking, an enormous expense a plant puts itself to in such a case as *Viola* in producing in the spring a large number of conspicuous flowers furnished with nectaries and all the complicated apparatus needed to insure cross-fertilisation, with the result, perhaps, of securing a very few cross-fertilised capsules. Having made these sacrifices, it proceeds during the summer to insure the production of a sufficient crop of less costly seeds by the inconspicuous aid of cleistogamic flowers.

Mr. Darwin, with characteristic ingenuity, adduces another instance of this balancing of conflicting advantages in the effort to secure before all things the perpetuation of the race. A seed in the ground—to parody a common proverb—is worth a good many exposed to depredation above it; and though dissemination is a gain, secure sowing is no less important. Many cleistogamic plants, therefore, having deliberately given up the advantage of cross-fertilisation, give up those attaching to change in the place of growth, and bury their fruits even before they are mature. This is the case with *Viola odorata* and *hirta* and *Oxalis Acetosella*. In other instances—and Mr. Darwin will pardon the remark that he has scarcely dwelt on the distinction—the buried fruit is the product of *subterranean* flowers. This is the case with *Vandellia sessiflora*, *Linaria spuria*, *Vicia amphicarpos*, *Lathyrus amphicarpus*, and *Amphicarpæa*, the three last cases belonging to *Leguminosæ*. The distinction is important because, while flowers produced under such abnormal circumstances as on subterranean branches must be necessarily cleistogamic, it by no means follows that aerial flowers which subsequently bury their fruits should also be cleistogamic, and Mr. Darwin very properly excludes the well-known earth-nut (*Arachis hypogæa*) from his list, as, though the ovaries are buried, the flowers are conspicuous. In such cases it is possible that the comparative humidity of the soil favours the maturation of the capsules, and especially so with small herbaceous plants in dry climates. Mr. Bentham in fact has pointed out in the case of *Helianthemum* that a prostrate habit which brings the capsules in contact with the surface of the ground postpones their maturity, and so favours the seeds attaining a larger size. *Cyclamen* (in every species except *C. persicum*), by the spiral contraction of its peduncle, brings its capsules down to the surface of the soil, though it does not appear to actually bury them, as some authors have supposed to be the case. If this is advantageous we need not wonder that the local amphicarpic races of *Lathyrus sativa* (of which there seem to be several) found in such dry countries as Portugal on the one hand, and Syria on the other, should acquire the habit of bearing actually subterranean fruit.

The steps, however, by which such a specialised mode of burying the fruit has been attained as exists in *Arachis*, are not easy to follow. Of few plants have the structure and habit been more misunderstood. Descriptive writers, from Rumphius to Endlicher, have represented it as having two kinds of flowers—and as being in fact what Mr. Darwin would call andromonœcious. It really, however, appears according to the careful examination of Poiteau and Bentham to have only flowers of one kind. These are apparently stalked, but the long stalk is in reality the attenuated calyx tube, which is a very peculiar feature for a leguminous plant. At the bottom of the calyx tube is the ovary which, after fertilisation, is gradually carried away by the development of a gynophore or subovarian stalk. It is the elongation of this gynophore—and not as Mr. Darwin states, by an oversight, the flower-stems drawing the flower beneath the ground—which buries the ovary. The careful observations of Correa de Mello show that though the gynophore may become three to four inches long, the ovary does not enlarge till it is buried, which confirms what has been said above as to the meaning of the habit generally. The details of the process by which the gynophore manages to bury the ovary would be a most interesting subject for investigation.

The obscurity which has attached to *Arachis* has also extended to *Voandzeia*, another leguminous plant cultivated like *Arachis* in hot countries for its subterranean pods. Mr. Darwin remarks that the perfect flowers are said never to produce fruit (pp. 327 and 341). Correa de Mello, however, never succeeded in detecting the cleistogamic flowers, and declares that it is "placed beyond all doubt that the hermaphrodite petaliferous flowers *do* produce fruit."[1] Perhaps therefore *Voandzeia* may have to be expunged from the list of cleistogamic plants, while on the other hand *Kraschenínikowia*, according to a thoughtful criticism of Mr. Darwin's book in the *Journal of Botany*, must be restored to it.

It may also be noted that according to Bentham *Martinsia* was a genus founded on a cleistogamic state of *Clitoria glycinoidis; Cologania* also should possibly be added to the list since Zuccarini's *Martia mexicana* appears to be an apetalous condition of some species of the genus.

Although the habit of producing cleistogamic flowers is pretty widely diffused amongst flowering plants it is locally concentrated in particular groups. This is particularly true in the case, as Mr. Darwin has pointed out, of *Malpighiaceæ* and *Acanthaceæ*, and amongst *Leguminosæ* in the *Glycineæ*. The genus *Viola* is remarkable in this respect; it is rich in cleistogamic species except in the section *Melanium*, to which *V. tricolor* belongs. In this species, besides conspicuous flowers adapted for self-fertilisation, smaller and less conspicuous flowers adapted for self-fertilisation are produced. These are not closed, but, as Mr. Darwin points out, "they approach in nature cleistogamic flowers," and though they differ in being produced on distinct plants they are perhaps destined to be as completely modified as the self-fertilising flowers of other sections of the genus.

The question as to the causes predisposing to the production of cleistogamic flowers is one of very great interest. In the first place Mr. Darwin points out that the larger proportion of known cases belong to plants with irregular flowers, that is, to plants whose flowers have been adapted for insect cross-fertilisation. Cleistogamy in this light is a resource to fall back upon when the elaborate adaptations for making insects do their work fail, as they seem to do more or less in *Viola*. It is a remarkable contrast that in heterostyled flowers, which are absolutely dependent upon insects for their legitimate fertilisation, irregular flowers are extremely exceptional, the adaptation, as far as it goes, being so complete that anything further in that direction is superfluous.

Four cleistogamic genera are normally wind-fertilised, and this shows that the cause alluded to above must be a subordinate one. Mr. Darwin urges with much force as the most potent agency, the unfavourable influence of climatic changes. From the time of Linnæus, it has been observed that exotic plants may be fertile, though their flowers have never attained proper expansion, that is to say, for the nonce they have become cleistogamic and self-fertile. The same thing occurs on a large scale with *Juncus bufonius*, in Russia, which in some districts never bears perfect flowers, while in Liguria, *Viola odorata* never bears cleistogamic ones. It is perhaps, however, doubtful whether winter-flowering plants are absolutely sterile, since the well-known *Chimonanthus*, whose name records its habit, is known to fruit, though sparingly, in this country. The evidence is, however, strong enough to render it highly probable that plants which are normally cross-fertilised, are driven into the abasement of cleistogamy when their geographical limits are extended beyond the limits not favourable to their receiving visits from appropriate insects, or to their properly expanding their flowers.

Here our comments must cease, content for our part if they attract a few more readers to a most fascinating research.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Elements of Articulate Speech

As a corollary to the interesting observation with the phonograph recorded by Prof. Fleeming Jenkin and Mr. Ewing in the last number of NATURE, will you allow me to point out that every capital letter of the Greek alphabet except Γ and P is actually (either as written or when turned through an angle of 90°) a reversible or a reduplicate symbol.

With regard to gamma, although the capital is not, the small letter (γ) *is* reversible; and as to P (or R, which is another ancient Greek form of it), many facts seem to show that by itself it does not as a rule represent a complete part of articulate speech; witness its frequent reduplication in Greek, the aspirate so often employed with it both in Greek and Latin, and the way in which it is frequently omitted, as if of no importance, from Latin words ordinarily spelt with it. The French or Italian pronunciation of this letter amounts to a reduplication in the English ear, while the English pronunciation of it amounts to its omission altogether in the ear of a Frenchman, an Italian, or a Scotchman.

In the Roman alphabet F, G, L, P, and R, are the exceptions; much might be said about each of these, but I will content myself by saying that L is obviously only an apparent exception, as it is easily derived from Λ. W. H. CORFIELD

Phoneidoscopic Representation of Vowels and Diphthongs

I HAVE just obtained the two following results with the phoneidoscope[1]:—

1. If a vowel be steadily sung on a single note, a constant colour-figure is produced; but if the vowel be spoken in the ordinary conversational tone, a change of figure occurs before the sound ceases. The slurring alteration of pitch which takes place in pronouncing a single vowel is thus rendered perceptible by the eye.

2. When a diphthong is slowly intoned, two distinct figures successively present themselves, which are found on trial to be those corresponding to its constituent vowel-sounds. The twofold nature asserted in the word "diphthong" receives by this experiment a visible illustration. SEDLEY TAYLOR

The Southern Drought

YOU ask in last week's NATURE (p. 436) for information respecting the drought in the southern hemisphere. A few days ago I received letters from Samoa and the Gilbert Islands telling me of its severity there. Droughts are of frequent occurrence in the Gilbert Islands, but my correspondent (a native of Samoa) tells me they have had an extraordinary one there, which commenced in 1876, and which continued up to the date of his letter—December 4, 1877. He says many of the people have died from starvation in consequence.

A letter from a missionary who has been forty years in Samoa contains the following:—"We have had the greatest drought I have ever known." The Samoan Islands are wonderfully fertile, and even during what is called the dry season it is rarely that more than a fortnight passes without rain. The atmosphere is always full of moisture, and there are very heavy dews at night, so that the vegetation never gets burnt up, except the drought be very extraordinary. Now, however, my correspondents speak of scarcity of food in those most fertile islands.

Blackheath, March 29 S. J. WHITMEE

[Can our correspondent favour us with the date of the last drought or series of droughts?—ED.]

Cumulative Temperatures

In reference to my letter upon the above subject, which was published in your columns of February 21 last, I have received from Prof. de Candolle, of Geneva, a communication dated March 11, in which he calls attention to the fact that in his "Géographie Botanique raisonné," which was published as far back as the year 1855, he recorded the suggestion (made by himself some ten years previously) of the employment of an uncompensated pendulum fitted with a suitable registering apparatus for the determination of cumulative temperatures in connection with the application of meteorology to agriculture and to the geography of plants.

In the above work (vol. i. pp. 58 and 59) the following passage occurs:—

"Les chiffres les plus importants à connaître pour les applications de la météorologie à l'agriculture et à la géographie botanique sont, pour chaque localité, les sommes de température au dessus de + 1°, + 2°, de + 3°, etc., par année, saison, mois ou fraction de mois.

"Pourrait-on obtenir ces valeurs directement par un instrument spécial, qui dispenserait de recourir à des calculs compliqués, souvent impracticables, dans le système actuel des observations météorologiques? C'est une question que je soumets aux physiciens. Elle m'a préoccupé depuis longtemps, mais je suis loin de posséder les connaissances théoretiques et pratiques nécessaires pour arrivir à une solution. J'entrevois la possibilité de construire deux sortes d'instruments qui répondraient aux conditions désirées; je les mentionne sans pouvoir indiquer les détails d'exécution.

"L'un de ces instruments serait la pendule-thermomètre de M. Edmond Becquerel, modifié de telle sorte que les battements par une température inférieure à 0°, ou ceux inférieures à + 1°, à + 2°, etc., ne seraient pas comptés."

"Un autre système serait celui de thermométrographes marquant les températures supérieures à tel ou tel degré, et seulement celles-là."

To this the following foot-note was added:—"Il y a plus de dix ans je fit des démarches auprès de deux astronomes, M. Gautier, à Genève, et M. Arago, à Paris, pour appliquer la pendule à la mesure des températures. Je proposais une pendule aussi dilatable que possible sous l'action de la température et un compteur adapté à l'instrument. . . . Les honorables savants auxquels je m'etais adressé penserent qu'il serait trop difficile de soustraire l'instrument à diverses causes d'erreurs."

From the above, which was written twenty-three years ago, it is clear that to the eminent botanist must be accorded the merit of priority not only of the suggestion but also of the publication of the idea of the method of averaging temperatures by observations of the pendulum, while to Mr. Stanley must be given the credit of embodying that idea in a practical form and constructing an instrument based upon the principle.

St. Leonards-on-Sea, March 10 CONRAD W. COOKE

The Wasp and the Spider

I HAD anticipated in my own mind Mrs. Hubbard's suggestion, and only the great pressure on your space prevented my meeting it in my previous letter. In the first place, my recollection is that the spider was of a kind that spins no web; like our own grey hunting spider, familiar in the summer on walls and palings. In the next place no species of spider, except the gossamers, habitually leaves this fine line behind it. It is in all cases a voluntary act, preceded by a perceptible pause, and pressure downwards of the extremity of the body to attach the end, whether for suspension, or in the process of forming the web. Even the gossamers are no exception to this rule; only in their case the line, in summer and autumn, is more continuously run out as a point of departure for their mysterious aerial flights. A house-spider, for instance, as he runs across the floor or across your hand, leaves no fine line behind him. The tiny gossamer has an amazing command of the material, but in the larger, web-spinning kinds it is far from inexhaustible, and, at all events, an apparently useless waste is not in the ordinary economy of nature. Moreover, in the case in question the spider was keenly aware he was pursued, and would not willingly leave so fatal a clue on his track. Mr. Merlin, who is on the list for 1878 as our consul for the Piræus, is, however, a competent observer, and could settle the question. HENRY CECIL

Bregner, Bournemouth, March 23

SUN-SPOTS AND RAINFALL

BY the overland mail which arrived here on January 12, I received, through the courtesy of Dr. W. W. Hunter, two copies of a pamphlet on "The Cycle of Drought and Famine in Southern India," a copy of the *Nineteenth Century* for November, and a copy of a letter on "The Rainfall in the Temperate Zone in Connection with the Sunspot Cycle," published in NATURE (vol. xvii. p. 59).

Having previously read notices of the pamphlet and being desirous to see it, I requested its author to favour me with a copy. His rainfall cycle for Madras was, so far as I could learn from newspaper reports, identical with a cycle which I had discovered long before. In my official report for 1875, which was printed and circulated in 1876, I gave a *résumé* of the results at which I had arrived from 1872 down to the close of 1875, and stated that an examination of returns from 144 stations in different parts of the world, as well as of the variations in the levels of European rivers, had led me to the conclusion that there was a rainfall cycle of the same duration as the sunspot cycle and nearly coincident with it, both the sunspots and the rainfall attaining a minimum in the eleventh, first, and second years of the cycle, and a maximum in the fifth year. Hence when I learned from an abstract of Dr. Hunter's results for Madras that in his "cycle of eleven years both the sunspots and the rainfall reach their minimum in the group consisting of the eleventh, first, and second years, and that both the rainfall and the sunspots there increase till they both reach their maximum in the fifth year," I was curious to know how his cycle had been made out; for although I had not the Madras rainfall for each year from 1813 to 1872, yet from the falls in the years of maximum and minimum sunspots which I got in the *Proceedings* and *Transactions* of the Institution of Civil Engineers (vol. xxxii.), I inferred that the Madras rainfall was not quite so favour able to my hypothesis as the rainfalls of some othe places. As, however, I might be wrong, I applied for complete table of the Madras rainfall, but withou success.

A remarkable rainfall cycle for Bombay, nearly coin cident with the sun-spot cycle, had been previously ascer tained, and a similar cycle, though not so well marked had also been found by comparing the yearly mean rain falls of Anjarakandy, Bombay, Calcutta, and Nagpu with Wolf's relative sun-spot numbers.

I have now the whole history of the Madras cycl before me. The author of the pamphlet says that afte many experiments he hit upon a method of working ou a cycle. This method consisted in commencing wit 1876, taking backwards, as far as the register extended periods of eleven years each, and then finding the mea rainfall for each series of years in the common period.

The results obtained for Madras by this method are t a considerable extent in conformity with those which had found for different countries; but there are discre pancies, one of the most remarkable of which is that th rainfall in the second year of Dr. Hunter's cycle is greate instead of less, than the mean rainfall. Still there is certain amount of coincidence. But as the method use by Dr. Hunter—and I would call special attention to thi point—is different from the one by which I found my cycle, his results and mine are not comparable.

The sun-spot cycle being one of about eleven years, and the maximum epoch occurring, on an average, 37 years after the previous minimum, and the next minimum 7·4 years after the maximum, I found by experience that the best way of comparing the rainfall and the sun-spots was to start either from a maximum or a minimum year, and the[illegible] take the proper number of years before and after the epochal year. Commencing with a maximum year, for instance, I took five years before it and seven years after it, or thirteen years in all. Then, with the view of reducing the effects of the so-called non-periodic variations, I took a mean of the rainfall in the first and third of the thirteen series, and a mean of that mean and of the rainfall in the second series, and so on. This gave me eleven new means, which I called the "mean cycle." Again, starting with a minimum year, I took eight years before it and four years after it, and found eleven other new means in the same way. To each set of results, or to a combination of both of them, I then applied interpolation formulæ, and found a well-marked coincidence between the sun-spot and rainfall variations.

As the sun-spot cycles are not all of the same length, it is evident that by starting from any one year and going backwards over a long period, always using the same fixed number, a maximum and a minimum year might fall into the same group.

Let me, by an example, explain my method more fully. I take the Madras rainfall :—

TABLE I.—*Rainfall Cycle at Madras.*

						max. years.							
1811–23	—	—	45·11	32·41	56·00	41·16	63·56	76·25	36·33	70·01	47·13	59·61	26·62
1824–36	33·72	56·05	60·71	88·41	37·80	36·87	32·43	44·35	18·45	37·11	39·00	41·47	44·76
1832–44	18·45	37·11	39·93	41·47	44·76	49·26	52·33	53·07	58·65	58·32	36·48	50·28	65·36
1843–55	50·28	65·36	38·05	70·81	80·90	54·76	39·81	36·88	64·32	72·09	35·82	43·20	32·32
1855–67	32·32	46·99	52·05	48·50	55·14	27·64	37·10	38·18	54·61	47·23	41·64	51·39	24·37
Means	33·69	51·38	47·17	58·12	54·96	41·94	45·06	49·75	46·47	57·07	40·01	49·19	38·69
Mean Cycle	—	46·12	50·00	54·50	52·49	45·07	45·55	47·75	49·94	50·15	46·57	44·52	—
Rainfall Variation	—	2·48	2·30	5·09	3·89	2·63	3·05	0·85	1·34	1·55	2·03	4·08	
Sun-spot Variation	—	32·3	19·2	1·1	30·2	40·0	20·8	11·3	1·2	1·8	21·1	23·6	
Years of Cycle	—	1	2	3	4	5	6	7	8	9	10	11	

It will be seen that the individual years of maximum sunspots, 1816, 1829, 1837, 1848, and 1860, are all in the same vertical column, and that all the years of minimum sun-spots, except 1810, contribute to the formation of the beginning and end of the cycle. No doubt it would have been better to have placed 1836 farther in advance, but this would have altered the position of the maximum year 1829.

The results given by the above method show a *double* oscillation of the Madras rainfall during the sun-spot period, and I see (NATURE, vol. xvi. p. 333) that Mr. J. Allan Broun has found such an oscillation for Trevandrum as well as for Madras, and this may be a characteristic of the rainfall of the whole of Southern India. We have, however, evidence of a single rainfall oscillation for other parts of India. Even Mr. Blanford now admits that there is a periodic variation underlying all irregularities and more or less coincident with the sun-spot variation.

In consequence of the method adopted by Dr. Hunter the years of maximum sun-spots, in place of being all in the same group, are spread over three or four of the groups from which he derived his mean cycle, and it is probably owing to this that he missed what, I think, is the real character of the rainfall cycle at Madras, as shown in Table I. The annual average rainfall for each year of his cycle, together with the deviations from the mean, is as follows, and it will be seen that his cycle is very different from the one given by my method :—

Years of Cycle.	1	2		4	5	6	7	8	9	10	11
	in.	in.	in.	in.	in.	in.	in.	in.	in.	in.	in.
Average Rainfall	49·15	35·00	49·08	49·17	58·33	50·95	50·37	54·35	52·88	45·16	37·03
Rainfall Variation	0·84	13·31	0·77	0·86	10·02	2·64	2·06	6·04	4·57	3·15	11·28

According to Dr. Hunter's cycle, the rainfall of Madras was in excess in the fifth year to the extent of *ten* inches, whereas, according to mine, it was nearly *three* inches in defect. He takes, it is true, the years 1868-76, which I do not take, preferring to wait till I get the rainfall of 1877; but although 1870, which he puts down in his fifth group, was a very wet one, the double oscillation still exists, one of the minima occurring soon after the sun-spot maximum.

I must now come to Dr. Hunter's letter in NATURE (vol. xvii. p. 59). But, first of all, I may be excused for saying that I do not think some remarks he made about a periodicity of cyclones in a former letter (vol. xvi. p. 455) were altogether calculated to put the matter in its proper light. He says (p. 456) :—" M. Poëy called the attention of the French Académie des Sciences to the subject five years ago, and published, as far back as 1873, a list of hurricanes in the West Indies from 1750 to 1873, in support of *his* views. Dr. Meldrum has worked the same question as regards the [East] Indian Ocean." Now if these words are meant to convey the impression that M. Poëy preceded me, and that I followed with the cyclones of the Indian Ocean, all I can say is that M. Poëy himself gave a different version of the matter.

In his second letter (vol. xvii. p. 59) Dr. Hunter states

(1) that the evidence with respect to the European rainfall may be considered as "against a well-marked periodicity," and (2) that the result of a "systematic inquiry (by himself) into the American rain-returns altogether fails to establish the existence of a common cycle, so far as concerns the temperate zone." On each of these points I beg to make a few remarks.

The evidence on which Dr. Hunter bases his statement as to the European rainfall is derived (1) from an examination by Mr. Baxendell, for a short period, of the rainfall at *one* English station, (2) from an examination by the late Dr. Jelinek of *fourteen* stations on the Continent, from 1833 to 1869, and (3) from a comparison of the levels of the Elbe, Rhine, Oder, Danube, and Vistula, with the sun-spots for six cycles, a comparison which Dr. Hunter ascribes to Herr Gustav Wex, but which I believe is due to another.

Now, the evidence is much more extensive. Instead of being based on one British station and fourteen stations on the Continent, it is based on more than fifty British stations and more than forty stations on the Continent, and, taken with the evidence furnished by the rivers, it is, in my opinion, conclusive.

As to the American rainfall, an examination of thirty-four returns has given me much more favourable results than those Dr. Hunter has got from twenty-two stations, and I have little doubt that he will, as he extends his investigations, also find favourable results; but I think he must first adopt a method different from the one he used for Madras.

In support of my conclusion that the rainfalls of Europe and America are subject to a periodicity which closely corresponds with the sunspot periodicity, I will for the present only submit to your readers two tables, the one showing the general results for Great Britain, the Continent of Europe and America, and the other the results for one station in each of these countries, namely Edinburgh, Paris, and New Bedford.

TABLE II.—*Comparison of the Variation in the Sun spot Area with the Variations in the Rainfalls of Great Britain, Continent of Europe, and America, from* 1824 *to* 1867 *inclusive.*

Years of Cycle.											
Sun-spots	31·7	19·5	3·5	28·8	39·5	29·5	10·4	4·9	14·8	21·2	19·4
Rainfall of Great Britain	2·22	1·07	0·04	1·10	1·05	1·46	1·28	0·80	0·43	0·73	1·03
Rainfall of Continent of Europe	0·76	1·73	1·22	0·44	1·18	0·97	1·08	0·60	0·45	0·36	0·62
Rainfall of America. .	2·73	0·88	0·91	0·53	0·24	1·34	2·03	0·84	0·27	0·66	1·24
Mean Rainfall Variation	1·90	1·43	0·69	0·71	0·82	1·26	1·46	0·78	0·10	0·05	0·55

The above results have been obtained in the manner in which I obtained the rainfall variation in Table I. For Great Britain the number of stations is 54, for the Continent of Europe, 42, and for America, 32.

TABLE III.—*Comparison of Variation in Sun-spot Area with Variations in Rainfalls of Edinburgh, Paris, and New Bedford, from* 1824 *to* 1867 *inclusive.*

Years of Cycle.	1.		3.	4.	5.	6.	7.		9.	10.	11.
Sun-spots	31·7	19·5	3·5	28·8	39·5	29·5	10·4	4·9	14·8	21·2	19·4
Rainfall of Edinburgh	3·02	1·66	0·64	2·50	3·45	2·80	0·64	0·27	0·91	2·36	0·56
Rainfall of Paris ...	0·25	0·61	0·30	1·27	2·22	1·90	1·40	0·84	1·42	0·94	0·48
Rainfall of New Bedford	3·07	1·03	0·66	0·32	0·19	1·38	3·47	2·87	0·32	1·42	0·08
Mean Variation of Rainfall...	2·11	1·10	0·54	1·15	1·83	3·05	1·87	0·59	0·88	1·57	0·25

It will be observed (see Table I.) that the variation in the Madras rainfall is not nearly so favourable as the variations for Edinburgh, Paris, and New Bedford.

What I have given here is but a small portion of the evidence in favour of a rainfall cycle. Having worked at the subject for six years, I have concluded that the whole evidence is as satisfactory as the evidence of a connection between sun-spots and terrestrial magnetism.

C. MELDRUM

Mauritius, February 1

JULIUS ROBERT VON MAYER

SEVERAL years ago (vol. v. p. 117) we published a paper by Prof. Tyndall on the nature and value of Mayer's researches, in which they were so fully detailed that now, on the occasion of the death of the man whose labours have won for him an undying renown, we need only briefly remind our readers of the chief events in his scientific career without entering into or attempting to renew a painful controversy of which it may be said that the truth lay neither wholly with one side nor the other.

Julius Robert Mayer was born at Heilbronn, November

25, 1814. In the neighbouring University of Tübingen, he underwent the usual course of studies in the medical faculty; and after obtaining his degree as physician, passed some time in the hospitals of Münich and Paris. His entrance into professional life was as ship's surgeon on an East India vessel. While thus engaged he made an observation apparently unconnected with, but really the origin of, all his subsequent investigations. To quote from Prof. Tyndall's paper referred to:—

"In the summer of 1840, he was at Java, and there observed that the venous blood of some of his patients had a singularly bright red colour. The observation riveted his attention; he reasoned upon it, and came to the conclusion that the brightness of the colour was due to the fact that a less amount of oxidation sufficed to keep up the temperature of the body in a hot climate than in a cold one. The darkness of the venous blood he regarded as the visible sign of the energy of the oxidation. It would be trivial to remark that accidents such as this, appealing to minds prepared for them, have often led to great discoveries. Mayer's attention was thereby drawn to the whole question of animal heat. . . ."

It was the idea thus suggested which he worked out to its issue in his great generalisation. In 1841 he returned from Batavia, and settled in his native town Here he devoted the spare hours from his professional duties to the consideration of various unsolved physical problems. Although almost entirely isolated from scientific companionship, with next to no opportunity for experimental research, and limited in time, he evolved in a short period a succession of theoretical views, which in point of originality, boldness, and comprehensive grasp of facts, stand among the foremost in the history of physics. Mayer's first contribution to scientific literature—"Ueber die Kräfte der unbelebten Natur"—appeared in Liebig's *Annalen* in 1842, and contained within the space of eleven pages the forecast of the mechanical theory of heat, as accepted at present. At this time the caloric theory still found numerous advocates, despite the classic experiments of Rumford, of Davy, and of others; and but a small minority ventured to defend, from one standpoint or another, the idea of an intimate connection between heat and motion. It was reserved for Mayer to sum together the scattered facts, and to mould from them definite views on the nature of heat. With his introduction of the expression "the mechanical equivalent of heat," and the clear exposition of the mutual interchangeability of heat and mechanical energy, he dealt the last blow to the old theory, and thus largely helped to place on a firm foundation the new doctrines of the conservation and transformation of energy. But in this Mayer did not stand alone, nor was he the only one who had a firm hold of the conceptions which have been so fruitful of result. The quiet sap of experiment was going on side by side with these daring reconnaissances beyond the borders of the known and proved, and our own Joule, whose work does not suffer because he was not the sole worker and thinker in the field, was conducting those researches which have earned for him also an undying name and fame.

Three years elapsed before the appearance of Mayer's next work in 1845, on "Organic Movement in Connection with the Transformation of Matter." In this *brochure* of 100 pages, he details at greater length the new theory, and with a most extensive, varied, and novel series of illustrations from every branch of natural science and natural history, establishes the principles that all the so-called forces are interchangeable forms of energy—the one sole force—that energy is never created or destroyed, and that all natural phenomena are accompanied by a change of the form of energy. The logical consequences of the mechanical theory of heat were followed to their uttermost limits in Mayer's work "On Celestial Dynamics," in 1848. Here he seeks to solve the difficult problems of determining the thermal effects of the movements in the universe, the maintenance of the supply of solar heat, &c. One chief source of the latter he considers to be the heat evolved by the fall of innumerable meteorites &c., into the sun.

His "Remarks on the Mechanical Equivalent of Heat," in 1851, was his last notable contribution to the development of this subject. It possesses the same fulness of original ideas as its predecessors, and in point of vividness and clearness of conception and definition, can only be rivalled by Tyndall's "Heat as a Form of Motion." A collected edition of his writings, under the title of "Die Mechanik der Wärme," appeared at Stuttgart, 1867, and a second edition in 1874; this was followed by "Naturwissenschaftliche Vorträge" (Stuttgart, 1871), and two papers under the title of "Die Torricelli'sche Leere" and "Über Auslösung" (Stuttgart, 1876). The controversy on the priority of his discoveries led to disturbances in the mental health of the great *savant*, which, however, was in time completely restored. Dr. Mayer was of an original and witty turn of mind, unrestrained in a small company, but otherwise modestly retiring within himself.

In measuring the value of Mayer's scientific achievements it must not be forgotten that he published his theory at an epoch when physicists were directing their attention especially to this very subject, and that in Denmark and England the experiments were well advanced, which led to the complete establishment of our present knowledge of the character of heat and energy. It is, however, difficult to believe that any of his rivals in this province could have developed and amplified the theory in the masterly manner shown by this obscure German physician. In perusing his works, one scarcely knows which to admire most, the wonderful powers of classification and breadth of knowledge exhibited in every page, or the charming simplicity, clearness, and aptness of illustration with which abstruse theoretical questions are put within the comprehension of a tyro in science. Certainly in view of his life and surroundings, the contributions of Mayer to the progress of physics occupy a unique position in the history of science. To quote Dr. Tyndall again—

"Mayer grasped the mechanical theory of heat with commanding power, illustrating it and applying it in the most diverse domains. He began, as we have seen, with physical principles; he determined the numerical relation between heat and work; he revealed the source of the energies of the vegetable world, and showed the relationship of the heat of our fires to solar heat. He followed the energies which were potential in the vegetable up to their local exhaustion in the animal. But in 1845 a new thought was forced upon him by his calculations. He then for the first time drew attention to the astounding amount of heat generated by gravity where the force has sufficient distance to act through. He proved, as I have before stated, the heat of collision of a body falling from an infinite distance to the earth, to be sufficient to raise the temperature of a quantity of water equal to the falling body in weight 17,356° C. He also found in 1845 that the gravitating force between the earth and sun was competent to generate an amount of heat equal to that obtainable from the combustion of 6,000 times the weight of the earth of solid coal. With the quickness of genius he saw that we had here a power sufficient to produce the enormous temperature of the sun, and also to account for the primal molten condition of our own planet. Mayer shows the utter inadequacy of chemical forces, as we know them, to produce or maintain the solar temperature. He shows that were the sun a lump of coal, it would be utterly consumed in 5,000 years. He shows the difficulties attending the assumption that the sun is a cooling body; for supposing it to possess the high specific heat of water, its temperature would fall 15,000° in 5,000 years. He finally concludes that the light and heat of the sun are maintained by the constant impact of meteoric matter. I never ventured an opinion as to the accuracy of this theory; that is a question which may still have to be fought out. But I refer to it as an illustration of the force of genius with which Mayer followed the mechanical theory of heat through all its applications. Whether the meteoric theory be a matter of fact or not, with him abides the honour of proving to demonstration that the light and heat of suns and stars *may* be originated and maintained by the collisions of cold planetary matter."

His services were recognised by election to membership in the French Academy of Sciences and other foreign societies, and two years before his death the King of Würtemberg elevated him to the nobility. Mayer received the Copley Medal of the Royal Society in 1871.

OUR ASTRONOMICAL COLUMN

TOTAL SOLAR ECLIPSES.—The eclipse of the sun on July 29, in which the belt of totality traverses the North American continent from Behring's Strait to the Gulf of Mexico, is a return of the eclipse of June 16, 1806, which was observed in the United States by Bowditch and the well-known Spanish astronomer, Ferrer; in this year it was central, with the sun on the meridian in 65° 30′ W., and 42° 23′ N., and the duration of total eclipse exceeded five minutes. At its next return on June 27, 1824, it was total at apparent noon in 170° 4′ W., and 44° 42′ N., but the course of the central eclipse was almost entirely an ocean-track. In 1842, on July 8, the total phase passed over the south of Europe, and was observed by a great number of astronomers, amongst them by the Astronomer-Royal at the Superga, near Turin, and by Baily, at Pavia, and Arago, who was stationed at Perpignan, gave a graphic account of the circumstances attending the extinction of sunlight, which has been often quoted. At the ensuing return of the eclipse in 1860, the "Himalaya" expedition was organised, and numerous descriptions of the phenomenon are upon record; one of the best of them is that given before the Royal Society, as the Bakerian Lecture, by Mr. de la Rue. American observers will doubtless render good account of the eclipse in July next. Its last return in the present century will take place on August 9, 1896, when it will be total soon after sunrise in the north of Sweden and Norway, central at apparent noon in 112° 21′ E. and 65° 38′ N. between Nova Zemlia and the mainland of Asia, ending in 179° 3′ W. and 18° 35′ N. in the North Pacific.

We have already given in this column some particulars of the total phase as it will occur in the present year in the United States. The last total eclipse visible in that country took place on August 7, 1869, and is the subject of detailed description in a very interesting appendix to the *Washington Observations*. The line of totality in the eclipse of January 11, 1880, will just reach American ground before sunset; some fifty miles south of Monterey, in California, the eclipse will be total for about forty seconds, but the sun will be at less than 2° altitude, thus affording a similar case to that which some interpreters of Herodotus have supposed to have occurred in the eclipse of Thales at the site of the battle between the Medes and Lydians when "day was suddenly turned into night;" though of course a characteristic of every total eclipse, it does not frequently happen that after a long ocean track the total phase is just landed on the coast of a continent at sunset. But although January, 1880, will witness what is strictly the next total eclipse of the sun on the soil of the United States, it does not appear that there will be one favourably circumstanced for observation until the year 1923, on September 10. As it is possible some readers may be interested in seeing the particulars of this eclipse, in connection with the phenomenon in July next, or as the next following eclipse in which totality can be well observed in any part of the North American continent, we give elements, &c., here, derived upon a similar system of calculation to what has been applied to other eclipses in these columns.

G.M.T. of conjunction in R.A. 1923, Sept. 10, at 8h. 28m. 42s.

	°	′	″	
Right Ascension	168	6	55·4	
Moon's hourly motion in R.A ...		34	53·8	
Sun's „ „		2	14·9	
Moon's declination	5	38	34·0	N.
Sun's „	5	6	14·5	N.
Moon's hourly motion in decl. ...		11	5·1	S.
Sun's „ „ „ ..		0	56·8	S.
Moon's horizontal parallax		59	55·3	
Sun's „ „			8·8	
Moon's semi-diameter		16	19·7	
Sun's „ „		15	53·7	

Hence the central and total eclipse commences at 7h. 15·6m. in long. 154° 38′ E., lat. 48° 24′ N.; it falls with the sun on the meridian in 127° 54′ W., and 38° 5′ N., and ends at 10h. 15·7m. in 63° 25′ W., and 13° 50′ N. The following are also points upon the line of central eclipse:—

Long.	Lat.	Zen. Dist.	Long.	Lat.	Zen. Dist.
° ′	° ′	°	° ′	° ′	°
120 13 W. ...	34 0 N. ...	31·1	106 12 W. .	26 22 N. ...	49·7
116 52 ...	32 18 .	33·1	94 33	23 55 ..	54·9
112 25 ...	29 47 ...	34·7	81 14	16 41	71·1

Calculating directly for the first of these positions which is near the N.W. point of the island of Santa Cruz, off the Californian Coast, we find

Totality begins at 0h. 46m. 2·5s. } Local mean time
„ ends at 0h. 49m. 50s. }

The duration of the total eclipse on this coast will therefore be about 3½ minutes, with the sun at an altitude of nearly 60°.

GEOGRAPHICAL NOTES

CHINA.—Lieut. Gill, R.E., who, a short time back, arrived in British Burmah, after succeeding in traversing China from Shanghai to the Yünnan frontier, has furnished a Rangoon paper with an account of his journey. Lieut. Gill, in the first instance, proceeded, *viâ* Hankow, to Chung-king, in Szechuen, whence he made a trip to the northwards, visiting the fire-wells of Tsi-liu, at which place are also found brine-wells, from which good salt is made. Mr. Gill made his way to Sung-pao-ting, on the borders of the Koko Nor, and to Liang-ngan-foo, returning by a different route to Chêng-tu. Being joined by Mr. Mesney, the two began their long, perilous, and arduous journey to Burmah overland, in the course of which they passed Bathang, on the borders of Thibet, in about N. lat. 30°. Near Bathang ranges were crossed which were some 15,600 feet in height. The most common tree near Bathang is the pine, which in some places was seen in magnificent forests, and many of the trees were found to be about three feet in diameter.

A correspondent of the *North China Herald*, writing from Chefoo, says that a scheme is under consideration for working the coal-mines of the province of Shantung, which is well known to be rich in mineral wealth. Some 120 miles to the west of Chefoo there is a fine level plain, under which at no great depth is a bed of coal twenty feet thick. The natives have from time immemorial been digging holes and getting a little out here and there, but as they have no means of drainage, the pits have filled with water as soon as they reached the good coal. The Chinese Superintendent of Customs at Chefoo, has obtained permission to form a native company [illegible] carry out the work, with the aid of modern appliances. The scheme referred to is understood to include a tramway to the port of Chefoo. Another project on a larger scale has been formed under the auspices of e famous Li Hung-chang, for developing the coal and districts to the north-west of Tientsin, in the Chihli ce. Should the enterprises we have alluded to be suc- y carried out, some hopes may be entertained of a gradual development of the hidden resources of the Chinese Empire.

ANGOLA.—We learn that a young and energetic collector, Mr. Alfred Heath, started on board the *Biafra*, which sailed from Liverpool last Saturday, for the purpose of exploring the interior of Angola, and obtaining objects of natural history. Mr. Heath will stay at Ambriz for a short time, and make collections on the River Loge and on the coast, after which he will proceed inland to Bembe, a place recommended by the late Mr. Monteiro as presenting an excellent field for the naturalist.

AN ORGAN-PIANO

WHEN recently in Paris I was shown—I believe at the pianoforte factory of M. Herz—a piano with appliances for producing prolonged sounds like those of an organ, which appeared to me to be based on thoroughly sound scientific principles, and which was so great a success that, although the invention had only been perfected a very few weeks before, the firm were receiving orders for the new instruments much faster than they could execute them. The attempt to combine organ sounds with those of a piano has often before, I believe, been made, but usually, if not always, I am told, by combination with the piano arrangements of real organ appliances, the result being, of course, extreme difficulty in obtaining perfect harmony between notes produced by two such totally distinct methods. In the present instance the organ as well as the piano notes are produced by precisely the same means, the principle consisting in producing the organ or prolonged sound by a succession of extremely rapid blows of a hammer upon the same strings as produce the piano note. It will not be difficult, I think (notwithstanding my want of familiarity with such subjects), to make your readers understand exactly how this is accomplished. They will observe that if the pianist were able, instead of merely holding down a key, to produce upon it an extremely rapid succession of blows, far exceeding in rapidity anything which the finger can possibly effect, a prolonged note would be produced, and especially so if the number of blows given was so great as to be practically inseparable by the ear. Now in the instrument of which I am speaking this object is accomplished by means of a series of additional hammers (one to each string) mounted upon watch-spring levers, all of which are carried by a bar of brass lying across, but above and clear of the strings. To this bar is attached a rocking lever which is set in very rapid motion by means of an apparatus worked easily by a pedal. I was not shown the exact nature of this apparatus, but there are so many forms of small engines worked with immense rapidity by compressed air, any one of which would answer the purpose, that no great importance attaches to this point. The *modus operandi* is simple enough: the pianist works the pedal, and thus sets the transverse bar with its series of hammers into excessively rapid vibration. By holding down any key of the instrument, the string belonging to it is brought within range of its corresponding hammer, and is struck with corresponding rapidity, giving out what sounds at a short distance like one prolonged note, which lasts as long as the pedal is worked and the key is kept down. It is easy to see that by this means it is in the power of the pianist to produce either piano or organ notes at will, and although while standing close to the instrument the mode of production of the note could be detected, at a short distance the effect was precisely that of combined piano and organ sounds with the immense advantage of absolute concordance and harmony between the two.

E. J. REED

THE COMING TOTAL SOLAR ECLIPSE

WE have received from Admiral Rodgers, the Superintendent of the U.S. Naval Observatory, the official circular which we were enabled to anticipate some little time ago. Owing to the endeavours of the American astronomers, the Pennsylvania Railroad Company have made arrangements for a reduced rate of fare to and from the East to Denver, Colorado, which is near the central line. These arrangements refer only to persons going in a private capacity, and not to members of expeditions sent out by foreign Governments.

Upon the order of the Superintendent of the U.S. Naval Observatory, Washington, the Company will furnish transportation to Denver and return *viâ* Pittsburg, Indianapolis, St. Louis, and Kansas City, or *viâ* Pittsburg, Chicago, and Omaha, at the following rates for the round trip:—From New York, 73.00 dols.; from Philadelphia, 71.00 dols.; from Baltimore or Washington, 62.50 dols.

The round trip ticket includes transportation (about 2,000 miles according to route) from New York to Denver and back again to point of starting; or in all, 4,000 miles of travel.

These arrangements allow the journey to Denver to be made by one route, and the return by another. The routes available are—

No. 1, *viâ* Pittsburg, Chicago, Omaha, Denver.
No. 2, *viâ* Pittsburg, Chicago, Omaha, Denver.
No. 3, *viâ* Pittsburg, Chicago, Omaha, Denver. (Different routes from Chicago to Omaha.)
No. 4, *viâ* Pittsburg, Chicago, Leavenworth, Denver.
No. 5, *viâ* Pittsburg, Chicago, Atchison, Pueblo, Denver.
No. 6, *viâ* Pittsburg, Indianapolis, St. Louis, Kansas City, Denver.
No. 7, *viâ* Pittsburg, Indianapolis, St. Louis, Kansas City, Denver. (Different routes from St. Louis to Kansas City.)
No. 8, *viâ* Pittsburg, Indianapolis, St. Louis, Kansas City, Pueblo, Denver.
No. 9, *viâ* Pittsburg, Indianapolis, St. Louis, Kansas City, Pueblo, Denver. (Different routes from Kansas City to Pueblo.)

Those intending to make observations of the eclipse, and desiring to take advantage of the courtesy extended by the Pennsylvanian Railroad Company, are requested to notify their intention by letter to the Superintendent of the U. S. Naval Observatory, asking that a letter certifying to their identity be forwarded to their consuls at the port they may select for arrival in the United States. This letter must, upon delivery, be countersigned by the consul of the applicant to prevent mistakes.

The Hon. Secretary of the Treasury has notified the collector of customs of the ports of Boston, Portland, New York, Philadelphia, and Baltimore, of the probable arrival of European observers, who will be identified by exhibiting the above letter, so signed and countersigned, to the collectors named. Orders have been issued to them as follows:—

"Upon the arrival at your port of any of the gentlemen mentioned, you will extend all proper facilities for the speedy delivery to them of the professional instruments in question free of duty and charges."

On presenting the same letter, so countersigned, to the agent of the Pennsylvania Railroad Company in New York, Philadelphia, Baltimore, or Washington, a round-trip ticket to Denver and return, will be issued to them by the Railroad Company at the rates before named.

From Denver railroad lines extend to points likely to be chosen for observing stations.

NOTES

Dr. Warren De la Rue, F.R.S., has just made a second donation of 100*l.* to the Research Fund of the Chemical Society, stipulating that the whole sum be devoted to a single object.

Mr. Romanes being prevented, by domestic affliction, delivering his lecture at the Royal Institution, on Friday, the 5th inst., as announced, the Hon. Sec., Mr. W. Spottiswoode, Treasurer of the Royal Society, has undertaken to lecture in his stead, on "Quartz; an old Chapter Re-written."

Prof. A. Agassiz has returned from his cruise in the Gulf of Mexico, and in spite of bad weather and the grounding of the *Blake*, he has done fully as much as anticipated. As we have already stated, he made use of steel rope for dredging; the rope, however, was only $1\frac{1}{8}$ inch circumference, not $1\frac{1}{16}$ inch in diameter as we were led to believe. This steel rope came up fully to his expectations, and he is of opinion that hemp rope is not likely to be again used for deep-sea work by any one who has no time to spare. Prof. Agassiz is preparing a preliminary report to the Superintendent of the Coast Survey of his trip.

The Iceland mail brings intelligence of a great eruption of Mount Hecla. On February 27, at 5 P.M., several smart shocks of earthquake were felt at Reykjavik, and in the same evening flames were visible behind the mountains, in the direction of Hecla. The Rev. Gudmund Jonsson, who lives close to Mount Hecla, states that at 4.30 P.M. of that day, slight shocks of earthquake began to be felt, these gradually increased till about 5 P.M., when two severe shocks occurred, creating a good deal of alarm, but doing no real damage. At 8 P.M. a tremendous eruption of flames appeared on the northern side of Hecla, the flames gradually increasing in size till they appeared like gigantic columns, double the height of the mountain. When the mail left Iceland on March 22, the eruption still continued, but apparently with diminished violence.

Copious rains have fallen in the eastern districts of Cape Colony, and hopes are now entertained of the speedy termination of the disastrous drought referred to in Nature, vol. xvii. p. 436. The heat in the east of the colony during January last is described as the most intense ever known in even that region of recurring scorching droughts.

The correspondent of the *Scotsman* at Ottawa describes a curious phenomenon which occurred in the end of February at Niagara Falls. In the vicinity of Table Rock the river-bed was dry for hundreds of yards towards the centre of the Horse-shoe Falls, whilst the river below the falls was about twenty-four feet below high-water mark. For three days the appearance of the river both above and below the falls led to the idea that the falls would entirely cease for a time. This extraordinary circumstance was attributed to incessant high winds from N.E. and an ice-gorge at the rapids above damming the waters of the river till its bed was nearly dry. The icicles which hung from the rocks over which the falls are wont to pour, added to the remarkable character of the scene.

A note sent by the Portuguese Government to the French papers states that a recent law has established in Mozambique and Angola a central council of agriculture, a station for conducting experiments, and a professorship of agriculture. In each capital public lectures will be given by the Government professor on zootechny and scientific agriculture.

The educational authorities of Berlin possess an enormous garden in one of the suburbs of the city for the purpose of supplying all the schools with fresh botanical specimens. The distribution takes place regularly after April 1, and over 4,000,000 plants are required for botanical instruction during the course of the year.

Prof. Ossian-Bonnet has been appointed to the Chair of Astronomical Physics in the Paris Faculty of Science and Letters.

A number of Algerian Arab chieftains have decided to visit the Paris Exhibition, and establish there a complete camp. They will bring with them a variety of Arab coursers.

Some time since we called attention to the opening of a village museum at Castleton, Derbyshire. The mode of its arrangement has attracted a good deal of attention, and we are glad to hear that it is doing good work in the neighbourhood. A series of scientific lectures in connection with it has been very successful.

The construction of the Tuileries captive balloon is attracting much attention in Paris. The necessary excavations for the rope-winding roller, the steam-engines, pulley, &c., &c., have modified the appearance of the old Tuileries yard. A large wooden saloon has been erected for the sewing of the canvas, which is quite ready; not less than 100 girls will be required for about a month. The work of making the rope, which is almost finished, has been immense. The weight of the netting will be 3,000 kilograms more than the displacement of the largest balloon in use. Besides the netting, the other ropes connecting the car, &c., will weigh 2,000 kilograms, and the large rope for mooring the balloon to the steam winding apparatus will be 3,000 kilograms. Experiments will be made to show that the rope can bear a traction of 50,000 kilograms, although it is not intended to ascend when the effort to move the balloon will exceed 12,000 kilograms. The real steam power required will be 300 horse-power. The displacement of the balloon will vary according to its station; on the ground it will be 24,430 cubic metres, but, floating at 600 metres in the air, it it will be 25,000.

Sir George Airy sends to the *Times* of Saturday a paper giving an account of the public standards of length now mounted, by authority of the Corporation of the City of London, in the Guildhall, and of the care that has been taken to insure their accuracy. The standards consist of a line of 100 feet divided into tens of feet, and a line of 66 feet divided into tens of links, with some smaller divisions, on the floor of the Guildhall; and measures of three feet, two feet, and one foot, with subordinate divisions, on the north wall of the Guildhall. The lengths have been verified with the most scrupulous care by the officers of the Standards Department of the Board of Trade, and there is reason to believe that even the longest is not in error to the amount of one-hundredth of an inch. Sir George Airy has inspected these standards, and is satisfied with the general excellence of their construction.

The meteor which was observed by Mr. Elliot at Hawick (p. 425) on March 25, at 10·20 A.M., was observed in various parts of Scotland, at Dunbar, Dundee, Cupar-Angus, and different parts of Fife. It is described as "apparently" several feet in circumference, cone-shaped, and at Dundee was observed to burst into a thousand fragments when near the earth.

M. Krantz, the Director-General of the Paris Exhibition, has been elected the president of a society for scientific excursions and demonstrations at the Champ de Mars. A circular has been issued by this organisation, which contains among its members a large number of influential scientific, industrial, and literary men. It is intended to organise a number of tours in the several sections under the guidance of experienced and competent teachers, the number of auditors admitted to each tour being limited to thirty. The charges will be very low, the society expecting to obtain for its professors and tourists a diminution of the entrance fee. Any communication may be sent to M. La Motte, editor, the secretary of the Association d'Excursions Scientifiques, Quai des Augustins, Paris. This society has been sanctioned by the Ministry of Public Instruction, and these excursions are quite distinct from the lectures which will be organised on a large scale, as we mentioned a few weeks ago.

THE museum in the Paris Jardin des Plantes has lately been enriched by two very valuable collections. The first includes a vast variety of anthropological and ethnographical objects gathered by M. Pinart during his voyages in Polynesia, among which might be mentioned more especially the ancient stone statues from Easter Island, executed by a race unknown to the present inhabitants. The second consists of over 40,000 specimens in natural history, collected by M. Raffray in New Guinea, chiefly birds and insects.

M. SOLEIL, the well-known optician of Paris, who invented and patented the optical saccharimeter, patronised by Arago, has died at St. Gratian. He was eighty years of age, and had retired for the last twenty years.

ONE of the newly-opened streets in the Luxembourg Gardens, Paris, close to the Observatory, has been called "Rue Herschel," as a compliment to English astronomy.

IN the February session of the Deutsche anthropologische Gesellschaft, Prof. Bastian gave an interesting address on the occurrence of similar weapons among widely-separated African tribes, describing more particularly a peculiar kind of javelin, found by Schweinfurth on the eastern coast, by Pogge in the Gaboon region, and by other explorers in the Fan tribe of the interior. On the Gaboon coast it is preserved at present as a fetish, being no longer used. This, as well as other examples, tends to show the common origin of all the African races. The remains of an art closely allied to that of ancient Egypt even, have been discovered on the western coast by Dr. Pogge, who has brought back images, on which the beard and coiffure were the counterparts of those decorating the Egyptian statues 3,000 years ago.

IT has been stated by Mr. Rodwell (NATURE, vol. ix. p. 8), that the ancient Egyptians were acquainted with the principle of the "rider" in the balance. According to M. Wiedemann (*Annalen der Physik*) who has examined over 100 representations of Egyptian balances, this is based on a mistake. The Egyptian balance is a simple equal-armed one; a hook on the upper part of the stand supports a cord with terminal weight, or a plumb-line. In representation (perspective being unknown to the Egyptians), the hook and weight, as seen from the side, were drawn in the plane of the balance, so that the weight, in badly made figures, seems to hang, not from the hook, but from the balance-beam.

WE have received the Report of the Registrar-General of the province of Ontario for 1876. To the usual tables with the Report is added an interesting appendix by Mr. T. H. Monk, on the influence of the weather on the mortality of Toronto. The results show, so far as can be looked for, from one year's mortality numbering only 1,664 deaths, a general correspondence with those obtained by Mr. Buchan and Dr. Arthur Mitchell in their large inquiry into the influence of weather on the mortality of London. We hope Mr. Monk's suggestions will be carried out and that the inquiry will be extended so as to embrace the whole province, the health as well as the mortality of the people, and the registrations of the more prominent, if not of all the diseases, be printed for each week, in order to test more decisively the connection between weather and health and how far changes in the health and mortality of the people and the spread of epidemics may be foretold, as well as changes of weather, now so efficiently carried on in North America.

SINCE Mr. Darwin demonstrated processes similar to digestion in the plant organism, attention has been largely given to the discovery of substances of the nature of ferment in plants. M. van der Harst, of Utrecht, has lately examined the seeds of the garden bean (*Phaseolus vulgaris*) in this respect. He finds in these, when in germination, a ferment which can be extracted by means of glycerine. It has the power of transforming albuminous matter into peptones, and starch meal into glucose. It occurs exclusively in the seed lobes.

A CORRESPONDENT sends us the following extract from a letter of one of the officers of the ship *Newcastle*, of London. It is dated Brisbane, Sunday, 30th December, 1877. "Last Friday (28th) in the afternoon, it came over very black, so we expected a thunderstorm. Well, it came on to blow from the south, and then to hail. At first the hailstones were about the size of a marble, but they continued to increase, until they became as large and exactly the shape of a tomato. The captain weighed three and found that the three together weighed one pound. I was on the poop, under the awning, but the awning was blown adrift, which compelled me to beat a hasty retreat. Nearly all the glass in our large saloon ports on the starboard side is broken. To-day, when I was on shore, the houses in Queen Street, facing the south, looked as though there had been a great fire, not a pane of glass left, and in many cases the frames gone altogether. Of course, the backs of the houses on the other side of the street must have suffered to the same extent. During the squall, which lasted about three-quarters of an hour, the river was one mass of foam, caused by the hailstones raining upon its surface in such numbers."

AN interesting archæological discovery has been made at Cancello in the neighbourhood of Naples, by the uncovering of the cemetery of the ancient city of Luessula. The excavations made thus far have brought to light an immense number of interesting objects of ancient Greek civilisation. At Clermont-Ferrand, also, in Southern France, an old Roman villa has been laid bare and found to possess a rich treasure in the way of ornaments, &c.

AN interesting geological discovery has recently been made at Donaueschingen (Baden). A complete and very well-preserved skeleton of the prehistoric musk-deer (*Cervus elaphus muscosus*) has been found in the neighbourhood of this little town. The horns are of gigantic size and show over forty ends; it is aserted that this skeleton is the first complete one known.

M. LUIGI PONCI describes, in *L'Elettricista*, a new electric battery of great simplicity. It consists of the usual glass jar and porous cylinder; the latter, however, is filled with a solution of ferrous chloride (35° Beaumé), and has for a pole an iron plate, while the external solution is of ferric chloride (also 35° B.), and contains a carbon pole. The electro-motive power is 0·9 of that of a Daniel cell.

A ST. PETERSBURG correspondent, "C. S.," desiring to purchase a dictionary of chemistry, writes that he would gladly avail himself of a critical comparison of existing works of the kind. He suggests that a comparative estimate might be given through the pages of this journal. At the same time one of our Paris correspondents writes us on the appearance in Paris of the 25th number of the French "Dictionnaire de Chimie pure et appliquée," edited by Prof. Würtz; closing with the article on Vanadium. This important work was commenced by Prof. Würtz in 1869, assisted by a corps of twenty-five leading French chemists, and although delayed materially by the war and its results, has been pushed forward vigorously, until it is now on the eve of completion. It will form altogether five volumes, numbering nearly 5,000 pages, and will be the first record of chemistry approaching completeness in the French language. The chemist is still dependent in a great measure on the English language, for the seven bulky volumes of Watts's "Dictionary," including its two supplements, form the most extensive as well as most recent compendium of chemical knowledge. Although Germany takes the lead in regard to chemical discovery, she is far behindhand in this respect. The new edition of the "Handwörterbuch," based on the well-known work of Liebig, Wöhler, and Kolber, now edited by Prof. Fehling, was commenced in 1871, but has progressed at a snail's pace, being only half way through the letter E, and the second of the six volumes which it will compose, not being yet completed. The Italian chemists have recently issued a dictionary of chemistry on a somewhat smaller scale than those alluded to above, but well edited and written.

THE additions to the Zoological Society's Gardens during the past week include two Pudua Deer (*Cervus humilis*) from Chili, a Black-faced Spider-Monkey (*Ateles ater*) from East Peru, deposited; an Arabian Gazelle (*Gazella arabica*) from Arabia, presented by Mr. W. W. Webb.

FOG SIGNALS[1]

DURING the long, laborious, and, I venture to think, memorable series of observations conducted under the auspices of the Elder Brethren of the Trinity House at the South Foreland in 1872 and 1873, it was proved that a short 5½ inch howitzer, firing 3 lbs. of powder, yielded a louder report than a long 18-pounder firing the same charge. Here was a hint to be acted on by the Elder Brethren. The effectiveness of the sound depended on the shape of the gun, and as it could not be assumed that in the howitzer we had hit accidentally upon the best possible shape, arrangements were made with the War Office for the construction of a gun specially calculated to produce the loudest sound attainable from the combustion of 3 lbs. of powder. To prevent the unnecessary landward waste of the sound, the gun was furnished with a parabolic muzzle, intended to project the sound over the sea, where it was most needed. The construction of this gun was based on a searching series of experiments executed at Woolwich with small models, provided with muzzles of various kinds. The gun was constructed on the principle of the revolver, its various chambers being loaded and brought in rapid succession into the firing position. The performance of the gun proved the correctness of the principles on which its construction was based.

Coincident with these trials of guns at Woolwich gun-cotton was thought of as a possibly effective sound-producer. From the first, indeed, theoretic considerations caused me to fix my attention persistently on this substance; for the remarkable experiments of Mr. Abel, whereby its rapidity of combustion and violently explosive energy are demonstrated, seemed to single it out as a substance eminently calculated to fulfil the conditions necessary to the production of an intense wave of sound. What those conditions are we shall now more particularly inquire, calling to our aid a brief but very remarkable paper, published by Prof. Stokes in the *Philosophical Magazine* for 1868.

A sound wave consists essentially of two parts—a condensation and a rarefaction. Now air is a very mobile fluid, and if the shock imparted to it lack due promptness, the wave is not produced. Consider the case of a common clock pendulum, which oscillates to and fro, and which therefore might be expected to generate corresponding pulses in the air. When, for example, the bob moves to the right, the air to the right of it might be supposed to be condensed, while a partial vacuum might be supposed to follow the bob. As a matter of fact, we have nothing of this kind. The air particles in front of the bob retreat so rapidly, and those behind it close so rapidly in, that no sound-pulse is formed.

The more rapid the shock imparted to the air, the greater is the fractional part of the energy of the shock converted into wave motion. And as different kinds of gunpowder vary considerably in their rapidity of combustion, it may be expected that they will also vary as producers of sound. This theoretic inference is completely verified by experiment. In a series of preliminary trials conducted at Woolwich on the 4th of June, 1875, the sound-producing powers of four different kinds of powder were determined. In the order of their sizes they bear the names respectively of Fine-grain (F.G.), Large-grain (L.G.), Rifle Large-grain (R.L.G.), and Pebble-powder (P.). The charge in each case amounted to 4½ lbs., four 24-pound howitzers being employed to fire the respective charges. There were eleven observers, all of whom, without a single dissentient, pronounced the sound of the fine-grain powder loudest of all. In the opinion of seven of the eleven the large-grain powder came next; seven also of the eleven placed the rifle large-grain third on the list; while they were again unanimous in pronouncing the pebble-powder the worst sound-producer. These differences are entirely due to differences in the rapidity of combustion.

These are some of the physical reasons why gun-cotton might be regarded as a promising fog-signal. Firing it as we have been taught to do by Mr. Abel, its explosion is more rapid than that of gunpowder. In its case the air-particles, alert as they are, will not, it may be presumed, be able to slip from places of condensation to places of rarefaction with a rapidity sufficient to forestall the formation of the wave.

As regards explosive material, and zealous and accomplished help in the use of it, the resources of Woolwich Arsenal have been freely placed at the disposal of the Elder Brethren. Gen. Campbell, Gen. Younghusband, Col. Fraser, Col. Maitland, and other officers, have taken an active personal part in the investigation, and in most cases have incurred the labour of reducing and reporting on the observations. Guns of various forms and sizes have been invoked for gunpowder, while gun-cotton has been fired in free air, and in the foci of parabolic reflectors.

On February 22, 1875, a number of small guns, cast specially for the purpose—some with plain, some with conical, and some with parabolic muzzles, firing 4 oz. of fine-grain powder, were pitted against 4 oz. of gun-cotton, detonated both in the open and in the focus of a parabolic reflector. The sound produced by the gun-cotton, reinforced by the reflector, was unanimously pronounced loudest of all. With equal unanimity, the gun-cotton detonated in free air was placed second in intensity. Though the same charge was used throughout, the guns differed considerably among themselves, but none of them came up to the gun-cotton either with or without the reflector. A second series, observed from a different distance on the same day, confirmed to the letter the foregoing result.

Meanwhile, the parabolic muzzle-gun, expressly intended for fog-signalling, was pushed rapidly forward, and on March 22 and 23, 1876, its power was tested at Shoeburyness. Pitted against it were a 16-pounder, a 5½-inch howitzer, 1½ lb. of gun-cotton detonated in the focus of a reflector, and 1½ lb. of gun-cotton detonated in free air. On this occasion, nineteen different series of experiments were made, when the new experimental gun, firing a 3-lb. charge, demonstrated its superiority over all guns previously employed to fire the same charge. As regards the comparative merits of the gun-cotton fired in the open, and the gunpowder fired from the best constructed gun, the mean values of their sounds were found to be the same. Fired in the focus of the reflector, the gun-cotton clearly dominated over all the other sound-producers.[1]

The whole of the observations here referred to were embraced by an angle of about 70°, of which 50° lay on the one side and 20° on the other side of the line of fire. The shots were heard by eleven observers on board the *Galatea*, which took up positions varying from 2 miles to 13½ miles from the firing-point. In all these observations, the reinforcing power of the reflector, and of the parabolic muzzle of the gun, came into play. But the reinforcement of the sound in one direction implies its withdrawal from some other direction, and accordingly we find that at a distance of 5¼ miles from the firing-point, and on a line, including nearly an angle of 90°, with the line of fire, the gun-cotton in the open beat the new gun; while behind the station, at distances of 8¼ miles and 13½ miles respectively, the gun-cotton in the open beat both the gun and the gun-cotton in the reflector. This result is rendered more important by the fact that the sound reached the Mucking Light, a distance of 13½ miles, against a light wind which was blowing at the time.

Theoretic considerations render it probable that the shape of the exploding mass would affect the constitution of the wave of sound. I did not think large rectangular slabs the most favourable shape, and accordingly proposed cutting a large slab into fragments of different sizes, and pitting them against each other. The differences between the sounds were by no means so great as the differences in the quantities of explosive material might lead one to expect. The mean values of eighteen series of tions made on board the *Galatea* at distances varying from mile to 4·8 miles, were as follows :—

---

[1] "Recent Experiments on Fog Signals." Abstract of paper read at the Royal Society, March 21. By Dr. Tyndall, F.R.S., Professor of Natural Philosophy in the Royal Institution.

[1] In this case the reflector was fractured by the explosion.

Weights	4-oz.	6-oz.	9-oz.	12-oz.
Value of sound ...	3·12	3·34	4·0	4·03

These charges were cut from a slab of dry gun-cotton about 1¾ inch thick; they were squares and rectangles of the following imensions:—4 oz, 2 inches by 2 inches; 6 oz., 2 inches by inches; 9 oz., 3 inches by 3 inches; 12 oz., 2 inches by 6 ches.

It is an obvious corollary from the foregoing experiments that n our "nesses" and promontories, where the land is clasped on oth sides for a considerable distance by the sea,—where, thereore, the sound has to propagate itself rearward as well as forard—the use of the parabolic gun, or of the parabolic reflector night be a disadvantage rather than an advantage. Here gunotton, exploded in the open, forms the most appropriate source f sound. This remark is especially applicable to such lighthips as are intended to spread the sound all round them as from entral foci. As a signal in rock lighthouses, where neither syren, team-whistle, nor gun could be mounted, and as a handy fleetignal, which dispenses with the lumber of special signal-guns, he gun-cotton will prove invaluable. But in most of these cases ve have the drawback that local damage may be done by the xplosion. The lantern of the rock-lighthouse might suffer from oncussion near at hand, and though mechanical arrangements night be devised, both in the case of the lighthouse and of the hip, to place the firing-point of the gun-cotton at a safe listance, no such arrangement could compete, as regards simlicity and effectiveness, with the expedient of a *gun-cotton ocket*. Had such a means of signalling existed at the Bishop's Rock Lighthouse, the ill-fated *Schiller* might have been warned of her approach to danger ten, or it may be twenty, miles before she reached the rock which wrecked her. Had the fleet possessed such a signal, instead of the ubiquitous but ineffectual steam-whistle, the *Iron Duke* and *Vanguard* need never have come into collision.

It was the necessity of providing a suitable signal for rock lighthouses, and of clearing obstacles which cast an acoustic shadow, that suggested the idea of the gun-cotton rocket to Sir Richard Collinson, Deputy Master of the Trinity House. That idea was to place a disk or short cylinder of the gun cotton, which had proved so effectual at low levels, in the head of a rocket, the ascensional force of which should be employed to carry the disk to an elevation of 1,000 feet or thereabouts, where by the ignition of a fuse associated with a detonator, the gun-cotton should be fired, sending its sound in all directions vertically and obliquely down upon earth and sea. The first attempt to realise this idea was made on July 18, 1876, at the firework manufactory of the Messrs. Brock, at Nunhead. Eight rockets were then fired, four being charged with 5 oz. and four with 7½ oz. of gun-cotton. They ascended to a great height, and exploded with a very loud report in the air. On July 27, the rockets were tried at Shoeburyness. The most noteworthy result on this occasion was the hearing of the rockets at the Mouse Lighthouse, 8½ miles E. by S., and at the Chapman Lighthouse, 8½ miles W. by N.; that is to say, at opposite sides of the firing point.

On December 13, 1876, and again on March 8, 1877, comparative experiments of firing at high and low elevations were executed. The gun-cotton near the ground consisted of ⅛-lb. disks suspended from a horizontal iron bar about 4½ feet above the ground. The rockets carried the same quantity of guncotton in their heads, and the height to which they attained, as determined by a theodolite, was from 800 to 900 feet. The day last-mentioned was cold, with occasional squalls of snow and hail, the direction of the sound being at right angles to that of the wind. Five series of observation were made on board the *Vestal* at distances varying from three to six miles. The mean value of the explosions in the air exceeded that of the explosions near the ground by a small but sensible quantity. At Windmill Hill, Gravesend, however, which was nearly to leeward, and 5½ miles from the firing-point, in nineteen cases out of twenty-four the disk fired near the ground was loudest; while in the remaining five the rocket had the advantage.

Towards the close of the day the atmosphere became very serene. A few distant cumuli sailed near the horizon, but the zenith and a vast angular space all round it were absolutely free from cloud. From the deck of the *Galatea* rocket was discharged, which reached a great elevation, a exploded with a loud report. Following this solid nucleus sound was a continuous train of echoes, which retreated to a continually greater distance, dying gradually off into silence after seven seconds' duration. These echoes were of the same character as those so frequently noticed at the South Foreland in 872-73, and called by me "aerial echoes."

On March 23, the experiments were resumed, the most noteworthy results of this day's observations being that the sounds were heard at Tillingham, 10 miles to the N.E.; at West Mersea, 15¾ miles to the N.E. by E.; at Brightlingsea, 17½ miles to the N.E.; and at Clacton Wash, 20½ miles to the N.E. by ½ E. The wind was blowing at the time from the S.E. Some of these sounds were produced by rockets, some by a 24-lb. howitzer, and some by an 8 inch Maroon.

In December, 1876, Mr. Gardiner, the managing director of the Cotton-powder Company, had proposed a trial of this material against the gun-cotton. The density of the cotton, he urged, was only 1·03, while that of the powder was 1·70. A greater quantity of explosive material being thus compressed into the same volume, Mr. Gardiner thought that a greater sonorous effect must be produced by the powder. At the instance of Mr. Mackie, who had previously gone very thoroughly into the subject, a Committee of the Elder Brethren visited the cotton powder manufactory, on the banks of the Swale, near Faversham, on June 16, 1877. The weights of cotton powder employed were 2 oz., 8 oz., 1 lb., and 2 lbs., in the form of rockets and of signals fired a few feet above the ground. The experiments throughout were arranged and conducted by Mr. Mackie. Our desire on this occasion was to get as near to windward as possible, but the Swale and other obstacles limited our distance to 1½ mile. We stood here E.S.E. from the firing-point while the wind blew fresh from the N.E. The cotton-powder yielded a very effective report. The rockets in general had a slight advantage over the same quantities of material fired near the ground. The loudness of the sound was by no means proportional to the quantity of the material exploded, 8 oz. yielding very nearly as loud a report as 1 lb. The "aerial echoes," which invariably followed the explosion of the rockets, were loud and long-continued.

On October 17, 1877, another series of experiments with howitzers and rockets was carried out at Shoeburyness. The charge of the howitzer was 3 lbs. of L.G. powder. The charges of the rockets were 12 oz, 8 oz., 4 oz., and 2 oz of gun-cotton respectively. The gun and the four rockets constituted a series, and eight series were fired during the afternoon of the 17th. The observations were made from the *Vestal* and the *Galatea*, positions being assumed which permitted the sound to reach the observers with the wind, against the wind, and across the wind. The distance of the *Galatea* varied from three to seven miles, that of the *Vestal*, which was more restricted in her movements, being from two to three miles. Briefly summed up, the result is that the howitzer, firing a 3-lb. charge, which it will be remembered was our best gun at the South Foreland, was beaten by the 12-oz. rocket, by the 8-oz. rocket, and by the 4-oz. rocket. The 2-oz. rocket alone fell behind the howitzer.

On the following day, viz., October 18, we proceeded to Dungeness with the view of making a series of strict comparative experiments with gun-cotton and cotton-powder. Rockets containing 8 oz., 4 oz., and 2 oz. of gun-cotton had been prepared at the Royal Arsenal; while others, containing a similar quantity of cotton-powder, had been supplied by the Cotton-powder Company at Faversham. With these were compared the ordinary 18-pounder gun, which happened to be mounted at Dungeness, firing the usual charge of 3 lbs. of powder, and a syren.

From these experiments it appeared that the gun-cotton and cotton-powder were practically equal as producers of sound.

The effectiveness of small charges was illustrated in a very striking manner, only a single unit separating the numerical value of the 8-oz. rocket from that of the 2-oz. rocket. The former was recorded as 6·9 and the latter as 5·9, the value of the 4-oz. charge being intermediate between them. These results were recorded by a number of very practised observers on board the *Galatea*. They were completely borne out by the observations of the Coastguard, who marked the value of the 8-oz. rocket 6·1, and that of the 2-oz rocket 5·2. The 18-pounder gun fell far behind all the rockets, a result probably to be in part ascribed to the imperfection of the powder. The performance of the syren was, on the whole, less satisfactory than that of the rocket. The instrument was worked, not by steam of 70 lbs. pressure, as at the South Foreland, but by compressed air, beginning with 40 lbs. and ending with 30 lbs. pressure. The trumpet was pointed to windward, and in the axis of the instrument the sound was about as effective as that of the 8-oz. rocket. But in a direction at right angles to the axis, and still more in the rear of this direction, the syren fell very sensibly behind even the 2-oz. rocket.

These are the principal comparative trials made between the gun-cotton rocket and other fog-signals; but they are not the only ones. On August 2, 1877, for example, experiments were made at Lundy Island with the following results. At two miles distant from the firing point, with land intervening, the 18-pounder, firing a 3 lb. charge, was quite unheard. Both the 4-oz. rocket and the 8-oz. rocket, however, reached an elevation which commanded the acoustic shadow, and yielded loud reports. When both were in view, the rockets were still superior to the gun. On August 6, at St. Ann's, the 4-oz. and 8-oz. rockets proved superior to the syren. On the Shambles Light-vessel, when a pressure of 13 lbs. was employed to sound the syren, the rockets proved greatly superior to that instrument. Proceeding along the sea-margin at Flamboro' Head, Mr. Edwards states that at a distance of 1¼ mile, with the 18-pounder gun hidden behind the cliffs, its report was quite unheard, while the 4-oz. rocket, rising to an elevation which brought it clearly into view, yielded a powerful sound in the face of an opposing wind.

On the evening of February 9, 1877, a remarkable series of experiments was made by Mr. Prentice, at Stowmarket, with the gun-cotton rocket. From the report with which he has kindly furnished me I extract the following particulars. The first column in the annexed statement contains the name of the place of observation, the second its distance from the firing-point, and the third the result observed :—

Stoke Hill, Ipswich ...	10 miles	Rockets clearly seen and sounds distinctly heard 53 seconds after the flash.
Melton	15 ,,	Signals distinctly heard. Thought at first that sounds were reverberated from the sea.
Framlingham	18 ,,	Signals very distinctly heard, both in the open air and in a closed room. Wind in favour of sound.
Stratford. St. Andrews..	19 ,,	Reports loud, startled pheasants in a cover close by.
Tuddenham. St. Martin	10 ,,	Reports very loud; rolled away like thunder.
Christ Church Park ...	11 ,,	Report arrived a little more than a minute after flash
Nettlestead Hall	6 ,,	Distinct in every part of observer's house. Very loud in the open air.
Bildestone...	6 ,,	Explosion very loud, wind against sound.
Nacton	14 ,,	Reports quite distinct—mistaken by inhabitants for claps of thunder.
Aldboro	25 ,,	Rockets seen through a very hazy atmosphere; a rumbling detonation heard.
Capel Mills	11 ,,	Reports heard within and without the observer's house. Wind opposed to sound
Lawford	15½ ,,	Reports distinct; attributed to distant thunder.

It is needless to dwell for a moment on the advantage of possessing a signal commanding ranges such as these.

The explosion of substances in the air, after having been carried to a considerable elevation by rockets, is a familiar performance. In 1873, moreover, the Board of Trade proposed a light-and-sound rocket as a signal of distress, which proposal was subsequently realised, but in a form too elaborate and expensive for practical use. The idea of the gun-cotton rocket with a view to signalling in fogs is, I believe, wholly due to the Deputy Master of the Trinity House.[1] Thanks to the skilful aid given by the authorities of Woolwich, by Mr. Prentice, and Mr. Brock, that idea is now an accomplished fact, a signal of great power, handiness, and economy, being thus placed at the service of our mariners. Not only may the rocket be applied in association with lighthouses and lightships, but in the Navy also it may be turned to important account. Soon after the loss of the *Vanguard* I ventured to urge upon an eminent naval officer the desirability of having an organised code of fog-signals for the fleet. He shook his head doubtingly, and referred to the difficult of finding room for signal-guns. The gun-cotton rocket completely surmounts this difficulty It is manipulated with ease and rapidity, while its discharges may be so grouped and combined as to give a most important extension to the voice of the admiral in command.

I have referred more than once to the train of echoes which accompanied the explosion of gun cotton in free air, speaking of them as similar in all respects to those which were described for the first time in my report on fog-signals, addressed to the Corporation of Trinity House in 1874.[1] To these echoes I attached a fundamental significance. There was no visible reflecting surface from which they could come. On some days, with hardly a cloud in the air, and hardly a ripple on the sea, they reached us with magical intensity. As far as the sense of hearing could judge, they came from the body of air in front of the great trumpet which produced them. The trumpet-blasts were five seconds in duration, but long before the blast had ceased the echoes struck in, adding their strength to the primitive note of the trumpet. After the blast had ended the echoes continued, retreating further and further from the point of observation, and finally dying away at great distances. The echoes were perfectly continuous as long as the sea was clear of ships, "tapering" by imperceptible gradations to absolute silence. But when a ship happened to throw itself athwart the course of the sound, the echo from the broadside of the vessel was returned as a shock which rudely interrupted the continuity of the dying atmospheric music.

The day on which our latest observations were made was particularly fine. Before reaching Dungeness the smoothness of the sea and the serenity of the air caused me to test the echoing power of the atmosphere. A single ship lay about half a mile distant between us and the land. The result of the proposed experiment was clearly foreseen. It was this. The rocket being sent up, it exploded at a great height; the echoes retreated in their usual fashion, becoming less and less intense as the distance of the surfaces of reflection from the observers increased. About five seconds after the explosion, a single loud shock was sent back to us from the side of the vessel lying between us and the land. Obliterated for a moment by this more intense echo, the aerial reverberation continued its retreat, dying away into silence in two or three seconds afterwards.

I have referred to the firing of an 8-oz. rocket from the deck of the *Galatea*, on March 8, 1877, stating the duration of its echoes to be seven seconds. Mr. Prentice, who was present at the time, assured me that, in his experiments with rockets, similar echoes had been frequently heard of more than twice this duration. The ranges of his sounds alone would render this result in the highest degree probable.

There is not a feature connected with the aërial echoes which cannot be brought out by experiments in the laboratory. I have recently made the following experiment :—A rectangle 22 inches by 12, is crossed by twenty-three brass tubes, each having a slit along it from which gas can issue. In this way, twenty-three low, flat flames are obtained. A sounding reed, fixed in a short tube, is placed at one end of the rectangle, and a "sensitive flame" at some distance beyond the other end. When the reed sounds, the flame in front of it is violently agitated, and roars boisterously. Turning on the gas, and lighting it as it issues from the slits, the air above the flames becomes so heterogeneous that the sensitive flame is instantly stilled by the aërial reflection, rising from a height of 6 inches to a height of 18 inches. Here we have the acoustic opacity of the air in front of the South Foreland strikingly imitated. Turning off the gas, and removing the sensitive flame to some distance behind the reed, it burns there tranquilly, though the reed may be sounding. Again lighting the gas as it issues from the brass tubes, the sound reflected from the heterogeneous air throws the sensitive flame into violent agitation. Here we have imitated the aërial echoes heard when standing behind the syren-trumpets at South Foreland. The experiment is extremely simple and in the highest degree impresssive.

THE IRON AND STEEL INSTITUTE

THE ninth annual meeting of the members of the Iron and Steel Institute was commenced on Thursday in the rooms of the Institution of Civil Engineers in Westminster. The chair was occupied by Dr. C. W. Siemens, F.R.S., the President of the Institute, and the proceedings were commenced by the reading of the Annual Report of the Council, which stated that the total number of members now exceeds 900, while a steady accession of new members continues, there being 47 proposed for election at the present meeting. The Council referred to the increase of foreign members, which shows the interest taken in the institute by Continental and American metallurgists. An invitation received from M. Tresca on behalf of the Société des Ingénieurs Civils, to visit Paris in the ensuing summer and the concurrent holding of the International Exhibition in that city, have induced the Council to recommend that the next autumn meeting should be held in Paris. A sum of 2,318*l*. has been raised by the Institute for the widow and family of Mr. Jones, the late general secretary,

---

[1] I have proposed that it should be called the "Collinson Rocket."

[1] See also *Philosophical Transactions* for 1874, p. 183.

The President stated that the Bessemer medal had been awarded to Prof. Tunner, of Leoben, Austria, in consequence of the great distinction that gentleman had earned for himself in his researches in that branch of science which the Institute so specially represented.

One of the most important papers read was by Mr. I. Lowthian Bell, M.P., F.R.S., on the separation of phosphorus from pig iron. In this paper Mr. Bell detailed his further experiences in his endeavours to eliminate the phosphorus from the iron, its presence having a weakening effect on the metal. Fully five-sixths of the pig iron manufactured in Great Britain is made from ores which, when smelted, give a product containing from three-tenths of a unit to nearly 2 per cent. of phosphorus. When, however, this element exists in pig iron to the extent of much more than one-tenth of a unit per cent. it is unfit for the Bessemer converter—at all events when ordinary spiegel iron, containing 10 or 12 per cent. of manganese, is used for its final purification. Bessemer steel rail-makers are, therefore, obliged to reject iron which formerly sufficed for the manufacture of iron rails, an iron comparatively free from phosphorus being necessary. That, therefore, affected the prosperity of the mines which formerly supplied the rail makers with ore, as well as the blast furnaces which produced the pig iron from that ore. Mr. Bell explained that at the high temperature of the Bessemer converter, while the carbon was removed by the air during its passage through the metal, the phosphorus was not affected. This he stated was also the case to a certain extent in the ordinary refinery furnaces; with a more moderate temperature, however, the conditions which bound carbon and phosphorus with iron were materially changed. The iron was more or less oxidised, and the oxide of iron so formed acted on the carbon and phosphorus. When the phosphorus is removed its loss is accompanied by a separation of the carbon contained in the pig iron. Loss of carbon, however, deprives the metal of its susceptibility of fusion at the temperatures at which the operation of refining and puddling are carried on, and when once the metal is solid the further elimination of phosphorus is very difficult, if not impossible. Mr Bell expressed the opinion that a lower temperature probably weakened the affinity of phosphorus for iron, as they existed in the crude metal, or strengthened the affinity between oxide of iron and phosphoric acid. A third condition involved in the mere condition of heat might be a diminution of the power possessed by oxide of iron in attacking the carbon, that element which enabled the crude metal to maintain fluidity when moderately heated. The author said that whichever one or more than one of the three conditions was required, the fact remained that melted crude iron might be maintained in contact with melted oxide of iron, and still retain carbon enough to prevent it solidifying, while the phosphorus rapidly disappeared. Instances were given of 95 per cent. of phosphorus being removed, while only 10 per cent of the carbon had been dissipated. The process consists in the more rapid agitation of the two substances while in a liquid condition. The iron so heated may be puddled for the production of malleable iron, or used for the manufacture of steel. Specimens of steel of the highest quality which had been so produced at the Royal Arsenal, Woolwich, were exhibited.

Dr. Percy, F.R.S., gave some particulars as to the manufacture of Japanese copper. Bars of this metal present a beautiful rose-coloured tint on their surface, which is due to an extremely thin and pertinaciously adherent film of red oxide of copper or cuprous oxide. This tint is not in the least degree affected by free exposure to the atmosphere. Dr. Percy placed before the meeting bars which he had possessed for thirty years, and which had undergone no change, although freely exposed to the atmosphere. The secret of this result lies in casting the copper under water, the metal being very highly heated and the water being also made hot. Dr. Percy stated that he had succeeded in casting copper in this way, and had produced similar results to those shown in the Japanese metal.

Other papers read were:—"On some Recent Improvements in the Manufacture of Iron Sponge by the Blair Process," by Mr. J. Ireland; "Statistics on the Production and Depreciation of Rails," by Mr. Charles Wood; "On Steel-casting Apparatus," by Mr. Michael Scott; "On Railway Joints," by Mr. C. H. Halcomb; and "On the Manufacture of Bessemer Steel and Steel Rails," by Mr. C. B. Holland.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Council of the Senate recommend that the application of Prof. C. C. Babington for skilled assistance at the Botanical Museum be granted, and that an assistant curator of the Herbarium be appointed at a salary of 100*l*. per annum, the appointment to be made by the Professor with the consent of the Vice-Chancellor, and to be for a period of four years. It is in contemplation to appoint a non-collegiate student.

BALTIMORE.—The Anniversary of the Johns Hopkins University was celebrated on February 22, when addresses were given by some of the professors and others. So far the progress of the University has been thoroughly satisfactory. One of its principal aims is to encourage original research, both among professors and students, and fellowships are granted to those who show aptitude for such work. Prof. Remsen, in his address, showed that a lofty idea of what original research really is, is entertained at the University; it is not merely the establishing of an isolated fact, the devising of a new piece of apparatus, the simple analysis of a new mineral, the discovery of an extra tooth in some abnormal animal; it is, rather, a systematic attempt to solve a definite problem, involving the use of a variety of methods peculiar to the special branch in which the attempt is made. In the three laboratories, biological, physical, and chemical, a variety of important work is being carried on, and altogether, both in the kind and amount of work which is being done under the auspices of the university, the trustees and professors show that they have a thorough appreciation of the spirit of the founder's legacy.

SOCIETIES AND ACADEMIES

LONDON

Mathematical Society, March 14.—Lord Rayleigh, F.R.S., president, in the chair.—Mr. Artemas Martin, Erie, Pa., was proposed for election.—The Secretary communicated a paper by Prof. J. Clerk Maxwell, on the electrical capacity of a long narrow cylinder and of a disc of sensible thickness. Prof. Cayley, Mr. J. W. L. Glaisher, Mr. Roberts, and the President made short communications.

Royal Astronomical Society, March 8.—Lord Lindsay, president, in the chair.—Mr. Neison read a paper on Hansen's terms of long period in the lunar theory. Mr. Proctor drew some diagrams referring to the position of the axis of Mars, and spoke upon Mr. Stone's paper of last January. Mr. Neison made some illustrative remarks thereon.—A paper by Mr. Plummer was read on the supposed influence of a mass of brickwork upon the errors of a transit instrument in its neighbourhood. Several Fellows commented upon this paper and described the lively behaviour of their transit-piers; Mr. Dunkin said there was nothing new about it.—A paper by Mr. Stone was read on telescopic observations of the Transit of Venus. Mr. Gill spoke on the difficulties concerning contacts, and some discussion followed.—A paper was announced by Prof. Sedley Taylor on Galileo's trial before the Inquisition in the light of recent researches; likewise an atlas of the ecliptic, by Heiss, of stars down to the fifth magnitude on Mercator's projection, made in order to get people to lay down the zodiacal light.—There were several other papers.

Entomological Society, March 6.—H. W. Bates, F.L.S., F.Z.S., president, in the chair.—Mr. John Woodgate was elected a Member of the Society.—Mr. F. Moore, at the request of Sir W. H. Gregory, late governor of Ceylon, exhibited a large series of drawings, executed by native artists, of the transformations of the lepidoptera of the island. These drawings were made under the direction of Dr. Thwaites, and represented, for the first time, the life-history of many species.—Mr. McLachlan exhibited some entomological parts of the great Russian work "Fedtschenkos' Travels in Turkestan."—Mr. H. Goss exhibited a small collection of fossil insects obtained by Mr. Gardner from the Bournemouth leaf beds (middle eocene). The collection comprised numerous elytra of coleoptera, and wings of neuroptera, &c.—Mr. J. Mansel Weale read some notes on South African insects. These referred to variation in *Pieris severina* and *Pieris mesentina*; to the secretion of formic acid in *Termes triniverius*, and the probable localisation of the same in a cephalic process, and also to the larvæ of some Hesperidæ in relation to the subject of protective resemblance.—Mr. Ed. Saunders read a paper entitled "Remarks on the Hairs of some of our British Hymenoptera." From a microscopical examination the author found that the presence of branched or plumose hairs is characteristic of the Anthophila, whilst the hairs of the Fossores, of Heterogyna, and of the Diploptera, are all simple, or in some cases twisted.—Mr. A. G. Butler communicated a paper on the natural affinities of the lepidopterous family Ægeriidæ. From an examination of structural characters, Mr. Butler considered that these insects presented no resemblance to the Sphingidæ, with which they had hitherto been allied, but were more related to the Pyrales and the Gelechiidæ. The president, in favour of this view, remarked that the whole of the Ægeriidæ had been made to depart from their congeners in appearance, through the action of mimicry.—The Secretary read a paper, by Mr. A. H. Swinton, on the biology of insecta, as determined by the emotions. The paper dealt chiefly with cases of simple muscular contractions and secretions.—Mr. Peter Cameron communicated a paper on some new genera and species of Tenthredinidæ.

Zoological Society, March 5.—Prof. Newton, F.R.S., vice-president, in the chair.—Mr. Sclater exhibited and made remarks on a second collection of birds from Duke of York Island, New Britain and New Ireland, which he had received from the Rev. George Brown, C.M.Z.S.—Mr. Sclater exhibited and made remarks upon a specimen of *Athene variegatæ*, and upon the type-specimen of *Fulica gallinuloides* of King, belonging to the Museum of Science and Art, Edinburgh.—Prof. Newton, F.R.S., drew attention to the statement of Legaut that every Solitaire (*Pezophaps solitaria*) carried a stone in its gizzard, and exhibited one of three stones found by Mr. Caldwell, C.M.Z.S., associated with the remains of as many birds of that species in the caves of Rodriguez.—Mr. T. J. Parker described the stridulating apparatus of *Palinurus vulgaris*, which consisted in a peculiar modification of the second joint of the antennæ working against the lateral surface of the antennulary sternum.—A communication was read from Mr. C. Spence Bate, C.M.Z.S., containing an account of the crustaceans of the Coast of Coromandel, collected by Sir Walter Elliot, K.C.S.I.—Mr. A. Boucard, C.M.Z.S., read notes on some coleoptera of the genus *Plusiotis*, and gave descriptions of three new species from Mexico and Central America.—A communication was read from Mr. Arthur G. Butler, F.Z.S., containing an account of a small collection of lepidoptera, obtained by the Rev. J. S. Whitmee, at the Ellice Islands.—A communication was read from Mr. Edward J. Miers, F.Z.S., on the *Penæidæ* in the collection of the British Museum.—Mr. George French Angas read the description of a new genus of land shells belonging to the family *Cyclophoridæ*, for which he proposed the name of *Mascaria*.—Mr. Angas also read descriptions of nine new species of land and marine shells from various localities, amongst which was a new *Rostellaria*, proposed to be named *R. luteostoma*, and a new *Bulimus* from Madagascar, proposed to be called *B. watersi*.—A communication was read from Dr. G. E. Dobson, C.M.Z.S., containing additional notes on the chiroptera of Duke of York Island and the adjacent parts of New Ireland and New Britain.—A communication was read from Mr. Robert Collett, C.M.Z.S., containing an account of *Latrunculus* and *Crystallogobius*, two remarkable forms of gobioid fishes found in Scandinavia.

Institution of Civil Engineers, March 26.—Mr. Bateman, president, in the chair.—The paper read was on direct acting or non-rotative pumping engines and pumps, by Mr. Henry Davey, Assoc. Inst. C.E.

PARIS

Academy of Sciences, March 25.—M. Fizeau in the chair.—The following papers were read:—Experiments designed to imitate various forms of foldings, distortions, and ruptures presented by stratified rocks, by M. Daubrée. He used an apparatus in which vertical and horizontal pressure could be produced, with screws, on sheets of metal of various thickness (especially lead), also sheets of wax mixed with plaster, resin, turpentine, &c. Various effects of a geological character were obtained.—Craniology: the Tasmanian race, by MM. de Quatrefages and Hamy. This relates to the sixth volume of the author's "Crania Ethnica." The Tasmanians formed a race by themselves, and remarkably homogeneous. Their cranial capacity is considerably over that of the Nubian negroes, yet the latter are socially much above the former. On the whole, the Tasmanian cranium does not present marked signs of inferiority. M. Hamy's measurements were made on at least fifty-four osseous heads and six skeletons.—On the treatment of wounds by occlusion, by M. Ravaisson-Mollien. In the winter of 1869, suffering greatly from chapped hands, he filled the wounds with filaments of wadding and then covered them with collodion. This gave relief and speedy cure. He communicated the fact to M. Nelaton, who, with M. Guerin, was then studying the treatment of wounds with occlusion of air.—Observations on the nature of the plants united in the group of *Nægerrathia*; generalities and type of *Nægerrathia foliosa*, Sternb., by M. De Saporta.—On the origin of the Phylloxera discovered at Bades (Eastern Pyrenees), by M. Planchon. This outbreak is shown to be due to introduction of some 500 vine-stocks from Gard, in France, five years ago. It is a mistake to regard the American vines as alone pestiferous. M. Duval Jouve was elected correspondent for the Section of Botany, in room of the late M. Hofmeister.—On a map of the erratic blocks of the valley of the Arboust, ancient glacier of Oo (environs of Lachon, Haute Garonne), by MM. Trutat and Gourdon.—M Dumas presented fascicle A of Measurements of the photographic negatives of the Transit of Venus.—M. Lecoq de Boisbaudran stated that he had prepared several anhydrous chlorides, bromides, and iodides of gallium. The atomic weight of gallium (according to two experiments) was 69 9.—Results of observations in 1877 on the sun's limb on the lines *b* and 1474 *k*, by M. Tacchini. The mean number of positions daily of these lines shows a minimum in agreement with that of the sun-spots. From maximum to minimum the diminution of visibility of *b* is greater than for 1474 *k*. Iron has an enormous preponderance at the base of the chromosphere; magnesium comes next. The other substances are of comparatively slight frequency, and they nearly disappear at the minimum of spots.—New considerations on the observation and reduction of lunar distances at sea, by MM. Beuf and Perrin.—On the effects of the rheostatic machine, by M. Planté. *Inter alia*, the difference in character of the electricity from the positive pole and that from the negative is more marked than with the electric machine or induction coil. (The forms of the sparks are described.)—On a *camera lucida*, by M. Pellerin. This describes an arrangement (copying M. Cornu's polariser) which gives two images of the same intensity visible at the same time by the whole pupil.—On a hydrate of ether, by M. Tanret. In filtering an etherised solution in free air, a crystallisation occurs at the upper part of the filter. This, got otherwise in larger quantity, was what the author examined, and found a true combination of ether and water of the nature of cryo-hydrates.—On the constitution of wool and some similar products, by M. Schutzenberger. Wool gives a fixed residue presenting the same elementary and immediate composition as that of albumen; the proportions of ammonia, carbonic acid, and oxalic acid are considerably higher than with albumen; acetic acid and pyrrol are in similar proportions.—On the formation of partitions in the stylospores of Hendersonias and Pestalozzias, by M. Crié.—On some new facts of perlitism of rocks, and on the artificial reproduction of perlitic fissures, by MM. Fouqué and Lévy. This reproduction is by treating hydrofluosilicic acid with excess of carbonate of lime, filtering the mixture (slightly diluted with water), receiving a drop of the liquid which passes on a piece of glass covered with Canada balsam, and letting dry.—On the period of rotation of solar spots, by Mr. Brown.—M. Gaiffe presented an apparatus which enables one to determine immediately, by a simple reading, the electromotive force of any electric generator.

THE APPLICATION OF ELECTRICITY TO RAILWAY WORKING

The Application of Electricity to Railway Working. By William Edward Langdon, Member of the Society of Telegraph Engineers; Superintendent (Engineering Department) Post-Office Telegraphs; and late Superintendent of Telegraphs on the London and South-Western Railway. (London: Macmillan and Co., 1877.)

IF any proof were needed of the vast and important services that science has conferred upon man, no more eloquent example could be instanced than that great combination of the conceptions of Stephenson and of Volta—the locomotive and the voltaic battery—which combination in its elaborated form is known as the railway system of the present time.

Living as we do in the midst of conveniences of transit, the mere belief in the possibility of which would, fifty years ago, have made a man a fit inmate for a lunatic asylum, we are apt to lose sight of the complexity of the problem that has been solved and to forget the all-important part which science has played in rendering such a state of things not only possible, but an accomplished fact of so familiar a nature as to have become a necessary part of our very existence. But when it is remembered that upon most of the lines of railway in and around London several hundred trains are running daily[1] at intervals varying from three minutes to half an hour, that each of those trains requires a separate series of signals only to protect it from collision, and that interspersed with the regular traffic "specials," "light engines," and trains out of time have to be provided for and protected against (to say nothing of the goods traffic, or of shunting, crossing and junction operations), it will be readily understood that traffic management, holding in its hands the power of life and death, is no easy task; and that without some very elaborate combination of sound administrative organisation with scientific instrumental aid, the traffic of a single hour would soon become an inextricable tangle of confusion.

Notwithstanding the great importance of the subject, involving as it does the safety of millions of human lives, it is somewhat surprising that technical literature should hitherto have been devoid of a work upon the very essence of safety in railway working—the application of the electric telegraph and of electric signalling to traffic management. This need has now been very ably supplied by the work before us, every page of which bears upon its face the evidence of being written by a thoroughly practical master of the subject in all its details and ramifications, and at the same time by one who possesses an exceptional power of making the subject clear to his readers.

In a handbook of a particular application of electricity it is refreshing to find that no valuable space is occupied by matter to be found in every elementary text-book of physics, that neither Thales with his amber nor Galvani with his frogs are even mentioned, and that descriptions of the various forms of the voltaic battery find no place in the book. The author presupposes that the necessary elementary knowledge is possessed or can be obtained by his readers, and disposing in one page of a few necessary introductory definitions plunges at once into his subject.

The work is arranged in three principal divisions:—(1) Speaking telegraphs; (2) Block signalling; and (3) Miscellaneous appliances. Under the first division a chapter is devoted to descriptions of the various speaking instruments and of the methods by which they are worked. The second chapter treats of signalling regulations, and while being of special value to all professionally engaged in railway working must prove most instructive and interesting to outsiders, who are thereby let into some of the technical mysteries of telegraphy. Every one is familiar with blank spaces left at the head of the telegraph forms issued by the Post Office, against which are printed the words "Prefix," "Code time," "Words," &c., but comparatively few know their meaning. The *Prefix* to a telegram is a signal letter or abbreviation to indicate the character of the message which follows, and therefore the order of its precedence for transmission. The *Code time* is a similar abbreviation to indicate the exact time at which a communication is handed to the telegraph clerk for transmission; and the space marked "Words" is set apart for signalling to the distant station the number of words contained in a message which gives to the receiving clerk a check upon his correct reading of the signals by which the communication is transmitted.

In railway telegraphy the prefix **D.R.** (**Danger**) gives to the message precedence over all others, and should never be employed except in cases of great emergency. Other prefixes **SP.** (for **special service**), **DB.** (for **ordinary traffic**), and various others are employed in railway signalling, by which the degree of its urgency is indicated before the message itself is transmitted.

The system upon which the **Code time** is abbreviated is very ingenious, and will be readily understood by referring to Fig. 1, which we have borrowed from Mr. Langdon's book. Opposite the hour figures on the dial of a clock are placed the twelve letters, A, B, C, D, E, F, G, H, I, K, L, and M, and against the four minute divisions between the hour figures, are placed the letters R, S, W, X, which, as will be seen in the sketch, are repeated all round the dial A simple time-code is thus obtained, by which any hour or minute throughout the day can be expressed in from one to three letters; thus 2 o'clock would be signalled by B, 2.45 by BI, and 7.12 (the time shown in the figure) by G, B, S, that is, G for seven hours, B for ten minutes, and S for the remaining two minutes to make up the twelve.

The technical regulations for railway telegraphing and traffic management are treated very fully. In this the author's large experience from having had the superintendence of the telegraphs of one of the most important lines of railway in the country is most apparent and gives great weight to his remarks, which ought to be committed to memory by all concerned in the management of railways; for if rigidly enforced and carried out, railway accidents would become well-nigh impossible, except from failure of instruments, from the breaking-down of rolling-stock, or from damage to permanent way.

---

[1] During some portions of the day as many as seventy-five trains run through Clapham Junction Station in an hour, and between 900 and 1,000 is the daily aggregate average.

The second division of the book is devoted to the consideration of the block system, first conceived by Sir William Fothergill Cooke, and to the instruments and regulations by which that system which is the great guardian of the safety of railway travelling is carried out. It begins with a short historical notice of the subject, and, after explaining some of the elementary principles upon which the various instruments are constructed, proceeds to describe the different systems for carrying the block system into effect. The chapters devoted to this subject are embellished by a large number of excellent illustrations; each system being treated in a chapter to itself, which is a tolerably complete treatise on the subject.

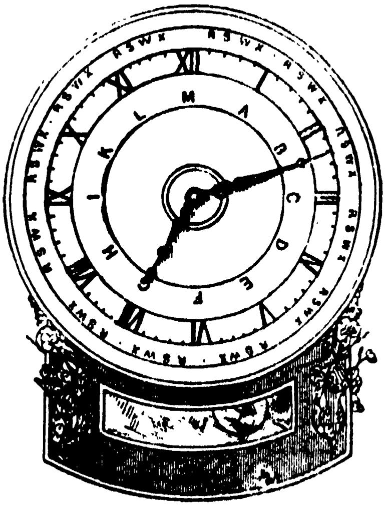

FIG. 1

The beautiful arrangements of Mr. Preece, in which the indications of the signalling instruments as well as their manipulation are identical with those of the outdoor signals, are clearly described, as well as the systems of Mr. Walker, of Messrs. Tyer, and of Mr. Spagnoletti, all of which are very extensively used in this country. The system of Messrs. Siemens Brothers so largely employed on the Continent, a description of which concludes this part of the book, is specially remarkable for the fact that in it batteries are dispensed with, the necessary electric currents for working the instruments being derived from small magneto-electric machines.

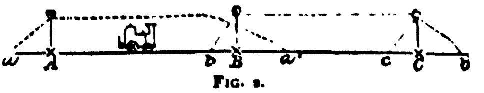

FIG. 2.

The various schemes that have been devised for making the train work its own signals, either by depressing "treadles" on the line, or by otherwise making electrical contacts, form a very interesting chapter, in which the systems of Mr. Imray, of London, of Mr. Rousseau, of New York, and of Dr. Whyte, of Elgin, are described and rendered clear by means of drawings and diagrams of the apparatus.

The essential principle of what is known as the block-system, is the insuring of there always being a certain distance between two trains travelling on the same line of rails. To carry this out the line is divided into a number of sections or "blocks," and the traffic is so regulated, that it is impossible for two trains to be in the same section at the same time. As a train enters one section, the signal behind it is set at danger, and is not lowered until the train has passed into the next section, which is similarly protected, and thus throughout the whole of its course a train cannot follow it at a distance less than the length of a section, or the distance between signal and signal. This is the one principle of the block system and all the various arrangements devised by different inventors differ only in the details by which it is carried out.

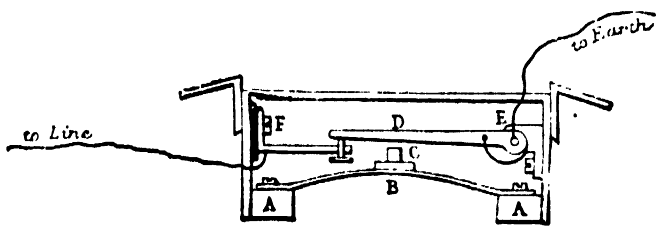

FIG. 3.

In Rousseau's arrangement, which may be taken as a type of the automatic systems of block signalling, the train in its progress depresses treadles on the line, which, by making electrical contacts with suitable apparatus, set the signals at danger as the train enters one section, and releases them as it passes into the next. A general idea of this system may be obtained by referring to Fig. 2, in which A, B, and C represent three signals, and the spaces A B and B C two sections of the line; at *a* is a treadle by which A is set at danger, and at *a* is another by which it is released; similarly a treadle at *b* sets the signal B at danger, and a second at *b*′ lowers it to the *all clear* position. A train, therefore, in passing *a*, which it does just before entering A B, will block that section against following trains by the signal A; travelling to B it will, in passing *b*, set B at danger, and not until it passes *a*′, when it is well out of the section A B, can the signal A be set at *all clear*, permitting a following train to enter A B.

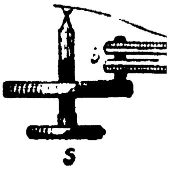

FIG. 4.

In the system of M. Brunius, which is under trial on the state railways of Sweden, telegraphic communication is made between the stations and the engine of the train, so that not only can ordinary signals be transmitted to the engine-driver, but he can receive instructions by telegraph.

Miscellaneous appliances employed in railway telegraphy are treated in the third division of Mr. Langdon's book, and an interesting chapter is devoted to the various "signal repeaters" and "light recorders." By the former, which were first employed by Mr. Preece, the position of the out-door signals is reproduced in miniature within the signal box, so that the signalman knows at once if the outside signals are correct. Light recorders are instruments which give warning, within the signal box, of the extinction of the light of the outside night-signals. Of these several forms have been devised but they all depend upon the expansion of metallic substances when subjected to the influence of heat and their subsequent contraction when that heat is removed. Fig. 3 is a cross-section of the transmitting portion of one of these instruments, in which B represents a concave disc of copper attached by its edge to the ring A A, a short distance above the flame of the lamp. When the light is out the lever D rests on the contact screw attached to the arm F (as shown in the figure) and the circuit is closed between the "line" and the earth, and an electric bell is set ringing in the signal box at the same time as an instrument indicates the words "*Light out.*" When, however, the plate B is heated by the flame below it, it becomes expanded, lifting the stud C, which, pressing against the lever D, lifts it off the contact screw, thereby breaking the circuit. The bell ceases ringing and the indicating instrument falls back to the signal "Light *in.*"

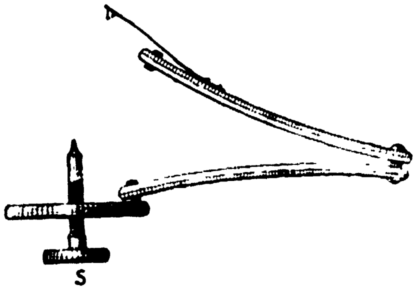

FIG. 5.

Figs. 4 and 5 represent a different arrangement for producing the same result, in which the contact-maker consists of two compact bars of dissimilar metals, constructed after the manner of a metallic pyrometer, and united together at the end A with the similar metals facing one another. By this arrangement the arc of motion is largely increased and the instrument is in consequence rendered more sensitive. Under the influence of heat the bars curve in opposite directions, as shown in Fig. 5, but on the light becoming extinguished their differential contraction brings them to the position shown in Fig. 4, contact is established, the bell rings, and the signal "Light *out,*" is transmitted to the receiving station.

The important subjects of the interlocking of points and signal levers, of level crossings, and the working of railway yards, all find their place in Mr. Langdon's book; and very interesting chapters are devoted respectively to the various kinds of electric bells, to lightning protectors or telegraphic instruments, and for the methods devised by different inventors and adopted by different railway companies for establishing intercommunication in trains.

It is not easy within the limits of the space at our disposal to do anything like justice to Mr. Langdon's most useful work, which is a thorough exposition of the subject in all its branches by one who not only has had a very large practical experience of the application of electricity to railway working, but who has the gift of clear description and a power of interesting his readers.

To all engaged in railway management whether directors, engineers, traffic managers, station-masters, signal-men, engine-drivers, or guards, Mr. Langdon's work will become a necessary text-book and book of reference, and the general scientific reader will find it most interesting and instructive. We must congratulate its author upon having put so much valuable information in so small a space, and its publishers upon having issued it in so cheap and attractive a form. C. W C.

TROLLOPE'S "SOUTH AFRICA"

South Africa. By Anthony Trollope. (London: Chapman and Hall.)

THERE are probably few of our Colonies the relations of which to one another are so little understood by the general public as those of South Africa, and none where events of so extraordinary a nature have occurred within the last few years. There are few Englishmen, therefore, by whom these charming volumes will not be read with delight and interest, coming as they do from a man of so much experience and of such liberal views as Mr. Trollope. The arrangement of the book is good and clear, each of the colonies being treated separately; a few chapters being devoted to a general introduction, and a few to the native tribes. The author has been led thereby into a somewhat unnecessary, possibly unconscious, repetition, when introducing each new district to his readers. This clearly arises from the fact that the origin of each colony is the same—the desire of the Boers to free themselves from British rule, their consequent occupation of new lands beyond the English border, and the necessity of our ultimately stepping in to govern them, both for their own good and for that of the natives. Mr. Trollope states that the objects of his interest are men and women, and it is to learn their condition, both socially and politically, that he visited South Africa.

Cape Colony, the oldest, largest, and most flourishing one, contains at present about 750,000 inhabitants, one third only of whom are white, and of the latter but one-third are English. These numbers indicate at once the very slow progress of the colony, and show that it is far from popular amongst emigrants, which Mr. Trollope thinks is due to the fact that here, and here only, the white labourer has to compete on equal terms with the native. The country seems closely to resemble the Riviera, though on a larger scale, both in scenery and capabilities. A great deal of the best lands, about 80,000,000 acres, is in private hands, of which only 550,000 acres are cultivated, being 1-145th of the private lands, and not one-fourteenth as Mr. Trollope has it. The great drawback to the country is the want of irrigation works when almost every European plant could be grown. Amongst other things, has not the cultivation of the olive been tried? We have nowhere seen any account of such an attempt. One would suppose that it would grow well, and in that case could not fail to be very remunerative. The people are well-to-do, and the rate of wages is good. When one, however, compares what is done here and in the United States in the way of irrigation works, in the scientific investigation of the country with reference to mining and agricultural pursuits, and in the collection and examination of the objects of scientific interest, one cannot but feel that there is a sad lack of enterprise and energy in the colony. The Cape Town Museum seems to be in a semi-starved condition.

The white population of Natal is almost entirely English, the Dutch having withdrawn for the most part as soon as the English Government decided on interfering. Sugar seems likely to form the staple of the colony. It is cultivated with the aid of coolie labour, although the Zulus are to the white population as sixteen to one.

In the Transvaal and the Orange Free State the Dutch form the agricultural, the English the town and trading population. Mr. Trollope seems to possess that genial disposition which draws out the bright side of the people with whom he is brought in contact. Although, therefore, he finds the Boer wanting in cleanliness, education, sociability, and enterprise, he finds in him many good points, and is far from thinking him so bad or so hopeless as the author of "The Great Thirst Land." The Boer has improved of late years, and in some cases considerable pains are taken with the education of the children. As Mr. Trollope says, "The Dutch Boer is what he is, not because he is Dutch or because he is a Boer, but because circumstances have isolated him."

Three chapters are devoted to the diamond diggings, and a very interesting plan of the great Colesberg Kopje is given. The author has very little sympathy with diamond-digging, and the only satisfaction he finds there is the civilising influence which the employment of so many natives cannot fail in time to exert. Mr. Trollope has devoted considerable thought and attention to the native question. His opinion is one well worthy of attention, though it is not likely, he thinks, to be regarded with favour either by Exeter Hall or the Colonists whose lands lie uncultivated for want of labour. He visited several of the Missionary Institutions, all of which, with the exception of M. Esselin's self-supporting one at Worcester, seem to have been more or less failures. He thinks that work, steady and regular but voluntary, will be found to be the best and most effective civilising agents. Unfortunately the natives' wants are so few and so easily satisfied, that there is at present no spur to regular work.

The account of Bloemfontein as a sanatorium for consumptive people is that of a man of "heroic mould" equal to the feat of dining twice daily, such as Mr. Trollope must be, seeing that at his age he makes light of, and seems to have enjoyed, the rough travelling by mail-carts, cape-carts, and otherwise, of considerably over two thousand miles. One regrets that he has not mentioned whether there is here the same change between morning, midday, and evening climate as he observed at Pretoria; also whether he came across any consumptive people, and how they fared. He also forgets that deal benches and chairs constructed with an equal regard to human anatomy, judging from the fact that easy chairs cost 13*l.* 10*s.* each, are not the seats most likely to conduce to the comfort of an invalid.

An excellent map accompanies the book. The type, paper, and "get-up" are all that can be desired, and the number of misprints is small.

W. J. L.

OUR BOOK SHELF

The Science of Language. By Abel Hovelacque. Translated by A. H. Keane. (Chapman and Hall, 1877.)

We have already had occasion to review at length the original French text of this work, which is now presented in an English dress. M. Hovelacque is one of the most distinguished representatives of the school of comparative philologists who would include their study among the physical sciences, and his book illustrates both the faults and the excellences of the view he upholds. In spite of the limitations thus introduced into the science of language, in spite, too, of the many inaccuracies which occur in his descriptions of the various groups of language at present existing in the world, the clearness and vigour of his style make his book one well worth translating, and it is satisfactory to see that it has been put into competent hands. Mr. Keane has added to the value of the work by a philological map, and a tabulated list of the languages described by M. Hovelacque, together with their characteristics and geographical position. From time to time, too, he has introduced foot-notes and even insertions in the text; many of these give fresh information or correct the statements of the author; others of them, however, had better been left unwritten. Thus his reference to Raabe's attempt to connect Aryan and Semitic grammar is not very happy, and he is unfair towards his author when he accuses him of inconsistency in being at once a Darwinian and a polygenist. No doubt "the impossibility of reducing man now to, say a mollusc, is no argument against the original identity of man with a mollusc" (or rather of his descent from the same form of life as a mollusc); but that is because there are intermediate links and stages of development between the mollusc and man, and M. Hovelacque believes—and with good reason—that such intermediate links do not exist between the manifold families of speech that are scattered over the world.

LETTERS TO THE EDITOR

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Age of the Sun in Relation to Evolution

It has been urged by Mr. Plummer (pp. 303 and 306) as a fundamental objection to the theory that sun-stars are formed from the collision of stellar masses, that if the theory be true there ought to be many of the stars moving with great velocities, which he affirms is not the case. But I am unable to understand upon what grounds he bases his assertion. I freely admit that if it could be proved that none of the stars has, as he seems to suppose, a proper motion of more than thirty or forty miles per second, it would at least be a formidable difficulty in the way of accepting the theory. For it would indeed be strange, as Mr. Plummer remarks, "that amid all the diversity of dimensions of the heavenly bodies, it should invariably happen that the resultant movement of the combined masses should be reduced to such insignificant figures as the above." But how does Mr. Plummer arrive at the conclusion that something like this must invariably have taken place? I fear that before his objection can be fairly urged something more definite must yet be known as to the rate of motion of the stars.

All that we are at present warranted to affirm, I presume, is simply that of the comparatively few stars whose rate of motion has been properly measured, none has a motion greater than thirty or forty miles per second, while nothing whatever is known with certainty as to the rate of motion of the greater numbers of stars. Before we can ascertain the rate of motion of a star from its angular displacement of position in a given time we must know its absolute distance. But it is only of the few stars which show a well-marked parallax that we can estimate the distance, for it is now generally admitted that there is no relation between the apparent magnitude and the real distance of a star. All that we know in regard to the distances of the greater mass of the stars is little more than mere conjecture. Even supposing we knew the absolute distance of a star and could measure its amount of displacement in a given time, still we could not be certain of its rate of motion unless we knew that it was moving directly at right-angles to the line of vision, and not at the same time receding or advancing towards us; and this we could not determine by mere observation. The rate of motion, as determined from its observed change of position, may be, say, only twenty miles a second, while its actual velocity may be ten times that amount.

By spectrum analysis it is true we can determine the rate at which a star may be advancing or receding along the line of sight independently of any knowledge of its distance. But this again does not give us the actual rate of motion unless we are certain that it is moving directly to or from us. If it is at the same time moving transversely to the observer, its actual motion may be more than 100 miles per second, while the rate at which it is receding or advancing, as determined by spectrum analysis, may not be twenty miles a second. But in many cases it would be difficult to ascertain whether the star had a transverse motion or not. A star, for example, 1,000 times more remote than *a* Centauri, that is, twenty thousand billion miles, though moving transversely to the observer at the enormous rate of 100 miles per second, would take upwards of thirty years to change its position so much as 1″ and 1,800 years to change its position 1′. In fact, we should have to watch the star for a generation or two before we could be certain whether it was changing its position or not. And even after we had found with certainty that the star was shifting, and this at the rate of 1′ in 1,800 years, we could not, without a knowledge of its distance, express the angle of displacement in miles. But from the apparent magnitude or brilliancy of the star we could not determine whether its distance was ten times, 100 times, or 1,000 times that of *a* Centauri and consequently we could form no conjecture as to the actual velocity of the star. If we assumed its distance to be ten times that of *a* Centauri, this would give a transverse velocity of one mile per second. If we assumed its distance to be 100 times that of *a* Centauri, this would give ten miles a second as the velocity, and if 1,000 times, the velocity of course would be 100 miles per second.

As there are but few of the stars which show a measurable parallax and having no other reliable method of estimating their distances, it follows that in reference to the greater number of the stars neither by spectrum analysis nor by observation of their change of position can we determine their velocities. There does not therefore appear to be the shadow of a reason for believing that none of the stars has a motion of over thirty or forty miles per second. For anything that at present is known to the contrary, the majority of them may possess a proper motion enormously greater than that.

There is, however, an important point which seems to be overlooked in Mr. Plummer's objection, viz., that unless the greater part of the motion of translation be transformed into heat, the chances are that no sun-star will be formed. It is necessary to the formation of a sun which is to endure for millions of years, and to form the centre of a planetary system like our own that the masses coming into collision should be converted into an incandescent nebulous mass. But the greater the amount of motion left unconverted into heat, the less is the chance of this condition being attained. A concussion which would leave the greater part of the motion of translation untransformed would be likely as a general rule to produce merely a temporary star, which would blaze forth for a few years or a few hundred years, or perhaps a few thousand years, and then die out. In fact we have had several good examples of such since the time of Hipparchus. Now, although it may be true that according to the law of chances, collisions producing temporary stars may be far more numerous than those resulting in the formation of permanent stars, nevertheless the number of those temporary stars observable in the heavens may be perfectly insignificant in comparison to the number of permanent stars. Suppose there were as many as one hundred temporary stars formed for one permanent, and that on an average each should continue visible for 1,000 years, there would not at the present moment be over half-a-dozen of such stars visible in the heavens.

JAMES CROLL

The Age of the Earth

WITH reference to the ingenious suggestion by Mr. Preston, on the earth's orbit having been practically diminished by ethereal retardation, there are a few other points to be considered. 1. That the minor planets could never have passed the major planets, as they would be certainly caught by them during the immense number of revolutions in which their orbits would be nearly equal. Therefore the earth cannot have dropped in from much farther than Jupiter's present orbit; for if during its revolutions it came within one-sixth of the distance from Jupiter that it now is from the sun, it would be mastered by Jupiter. 2. By the retardation of Encke's comet it seems that if the comet had the same orbit as the earth, its distance from the sun would diminish about $\frac{1}{28000}$ per year. But for any appreciable lengthening of the earth's life-period, the earth must have started much more than one-tenth farther from the sun than it now is; that is to say, it must fall in much quicker than at the rate of its present distance from the sun in 10^8 years. This shows that the individual portions of Encke's comet must be much more than two miles in diameter, even supposing it to have as great a mean density as the earth, and to consist of a shower of solid meteors. Thus if the earth's history should be lengthened by any important amount from this cause, the nucleus of Encke's comet must consist of a shower of bodies of as great a density as the earth, and of a considerable size, each weighing very much more than 100,000,000 tons. And considering that there must be thousands of such bodies to compose it, the total mass would be greatly beyond what is considered possible. 3. If the earth had drawn much nearer to the sun, the asteroids must have come in from a very much greater distance; and yet, though they differ greatly in size, they are all grouped closely together, whereas we should find then sorted out very much more widely, and a vast quantity of them retained by Jupiter as satellites.

The solar system appears to be really a quinary system of stars; the major planets being analogous to the sun in their characteristics of density, distances and proportions of satellites, and other elements, the minor planets being the sun's satellites. Thus it is seen that the uniform law of satellites is to regularly decrease in volume both close to, and farthest from, their primaries; the series manifestly terminating in asteroids in the case of the sun and of Saturn.

In the whole of the present discussion of the earth's age, what is the reason why only one out of several different limits is considered? 1. The decrease of temperature in the earth. 2. Tidal retardation. 3. The cooling of the sun, which is recognised as being the weakest of the three. 4. A uniform diffusion of temperature in the earth, which gives a limit, not for life, but for the separate existence of the earth. The close agreement of the limits of life history given by these first three methods is a very strong argument in favour of each of them; for if there is even a possibility of 1 in 5 that each separately is wrong, it would be less chance than 1 in 100 that the concordance of all three was wrong.

Is there anything so stable and certain in geologic time—when we remember that levels permanently alter as quickly as ten feet per century—that rainfall (and therefore denudation) depends mainly on the almost unknown changes in the sun's heat, a slight increase of rainfall making much greater rapidity of denudation—and that accumulation of peat and stalactite might well become proverbial for its variability—when all these uncertainties are remembered, is there anything so indubitable as to warrant our throwing all the odium of incorrectness on the cosmical chronology, and seeking to square it with geological suppositions?

W. M. FLINDERS PETRIE

Bromley, Kent

The "Eurydice" Squall

THE loss of H.M.S. *Eurydice* on the 24th ult. may perhaps give a melancholy interest to a plain statement of the facts connected with the meteorology of that day.

The squall in which she capsized was one of a common class which occur when, after a long steady fall of the barometer, the mercury pauses for a few hours before commencing to rise. These squalls differ considerably from simple squalls, and are frequently complicated, as in this case, with small secondary cyclones.

Since the 20th inst. the general type of weather over our islands had been very uniform, an area of high pressure being constantly found over the west of Ireland, with a constantly low pressure near Stockholm giving cold north-west winds, conditions which are very common in the month of March. But while the general shape of the isobaric lines remained constant, the absolute pressure over the whole area had been diminishing rapidly till the 24th inst. On the morning of that day, the centre of a cyclone was near Stockholm, while no less than three secondary depressions were influencing Great Britain, and by 6 P.M. the whole system had gathered itself into two small cyclones whose centres were near Yarmouth and Bergen.

Such a development of secondaries with a north-west wind is not common, and is always associated with exceptionally wild and broken weather, of the kind which gives heavy local rainfall, with squalls, or violent cold thunderstorms, but not widespread or destructive gales.

In London the changes above described were well shown by a steady fall of the barometer from the 21st inst., which amounted to an inch at 3.45 P.M. on the 24th. As a heavy squall came on then, the barometer jumped up suddenly two-hundredths of an inch, as is often the case in squalls, and then fell slowly in about a quarter of an hour to its former level, where it remained stationary till about 9 P.M., after which it rose steadily. The squall, which lasted about twenty minutes, was followed by very threatening-looking weather, during which the wind perhaps backed a little to west-north-west, but at 4.40 P.M. it shifted to north-north-east and became strong, with heavy snow, till 5.20, when the weather moderated, the whole being evidently due to the complicated action of one of the secondary depressions before mentioned.

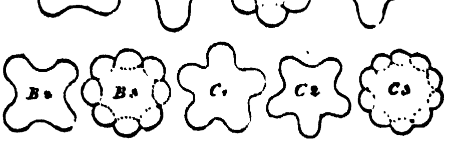
Materials are still wanting for tracing the connection between the squall in London at 3.45 P.M., and that at Ventnor at the same hour, but squalls often do occur simultaneously at distant places in connection with the trough of great non-cyclonic barometric depressions. The question of any such relation has not yet been worked out, and its solution presents great difficulties.

On the whole, then, the squall in which the *Eurydice* was lost, though of a common type, was somewhat exceptional in suddenness and violence. RALPH ABERCROMBY

21, Chapel Street, S.W., April 3

Leidenfrost's Phenomenon

A FEW days ago I was examining the "rosette" formed by a spheroid of water in a hot platinum capsule, and noticed that the outline was not a continuous curve, as is generally represented in books, but was "beaded" with re-entering angles as shown by the continuous lines in figures A_3, B_3, C_3, while the curve of each bead could be distinctly traced within the drop, forming a "fluted" outline, shown by the dotted lines in the same figures. It was at once manifest that both the "beaded" and "fluted" figures were produced by the superposition of the retinal images of the drop in two extreme conditions of vibration; that, in the case represented by A_3, the drop was really vibrating like a bell which is sounding its first harmonic above its fundamental note, and therefore possesses six ventral segments, the extreme forms assumed being represented by A_1 and A_2 respectively, and that B_3 and C_3 represent the appearance of the drop when vibrating like a bell which is sounding its second and third harmonic respectively. To verify this a spheroid of about five-eighths of an inch in diameter was produced; and as soon as the beaded decagon, C_3, was steadily maintained, the room was darkened, and the spheroid illuminated by sparks from Holtz's machine. Immediately the curvilinear pentagons C_1 and C_2 were apparent, and frequently the vibrations continued perfectly steady for several seconds. When the drop had diminished in size the mode of vibration changed, and the crosses represented by B_1 and B_2 appeared when the sparks passed; on opening the shutters the beaded octagon B_3 appeared almost perfectly steady in the capsule. The figures A_1, A_2, and A_3 were obtained in the same manner, and with a larger spheroid twelve and sixteen beads were obtained, presenting respectively curvilinear hexagons and octagons when illuminated by the sparks. In one case a small spheroid presented a very large number of beads in its outline; but on examining it with sparks it was found to be produced by the crosses B_1 and B_2 rotating very rapidly about a vertical axis. Two or three particles of carbon introduced into a spheroid remained for a long time close to the surface of one "ventral segment," like lycopodium powder on a Chladni's plate, and when they escaped from it were ensnared by the next segment. The figures observed when the spheroids were illuminated by sparks were fully as exorbitant as those shown at A_1, A_2, B_1, B_2, C_1, and C_2.



If the spheroidal form be due to the combined action of gravity and surface tension, it is obviously to the latter force that we must look for the production of vibrations when, by any accident, the spheroid is disturbed. The amount of steam produced from the under-side of any "ventral segment" will, of course, be greater the greater the surface exposed; and when this is a fresh surface, will increase as the surface becomes heated by exposure. Hence the amount of steam escaping from beneath a "ventral segment" will be greater as it is contracting towards, than when it is moving from, the centre of the spheroid, thus supplying, on the whole, during each vibration an impulse in the direction of motion. It seems unnecessary to look farther for a supply of energy. WM. GARNETT

Cavendish Laboratory, Cambridge, March 15

Trajectories of Shot

HAVING observed a letter in NATURE, vol. xvii. p. 401, in which extracts from a paper of mine are commented upon by the Rev. F. Bashforth, I trust you will let me make a few remarks by way of explanation.

In the paper referred to I was trying to weigh against one another the merits of different methods of finding the trajectories of shot, the calculations being, of course, based upon Mr. Bashforth's tables; and the method which I liked the best did not contain the equation (a), which is the text of Mr. Bashforth's letter. Now without doubt the method I preferred had faults of its own, but it was a sort of argument in its favour if I could show that the other methods were not faultless, and in particular if I could show that the equation (a), which is the key of those other methods, had no merits of severe accuracy to set off against certain defects which I thought it might fairly be charged with.

The objections I had to the equation (a) are partly set forth in the first extract quoted by Mr. Bashforth; but one great objection to it is the tediousness of its application in practice. Mr. Bashforth appears to be greatly offended with my description of the way the equation is used, viz., that it is a process of guessing. But he cannot pretend that he has solved the equation according to any strict method; he has only guessed at a solution which falls in more or less with his tables. It seems to me he is here quarrelling about a mere name, because the process he describes and indeed illustrates is practically the process I describe, and it is idle on his part to give me the information contained in his letter, because I am very well aware that the second guess gives a better result than the first. But as regards the amount of accuracy belonging to the equation, I must still hold by the substance and tendency of my remarks on that subject, except in my unfortunate use of the epithet "dangerous," which I admit was extreme. I frankly confess that the force of the argument derived from discussing the values of $\frac{dk}{dv}$ is materially weakened when those values are numerically exhibited and compared with the tables. At the same time, when taken in connection with the peculiar way the equation is used, the numbers, such as I make them roughly, do not convince me that the argument is without force. My chief criticism on the equation has two branches:—1. Mr. Bashforth has nowhere proved that he is entitled to use the k belonging to the mean velocity over the arc. 2. Granting that he may use that k, we have then to consider whether he has got v_0 and k to accord. For my part, I do not feel the degree of certainty which Mr. Bashforth expresses about this, especially if the work is carried over a considerable arc. I will grant that his result comes near the truth, but assuredly he cannot be said to have determined v_0 *accurately*, as he affirms.

I cannot help thinking that there is no real difference between Mr. Bashforth and myself, for all that I have said against the equation (a) can be said in another form against the method that I prefer, and I willingly indorse the statement in the last paragraph but one of his letter. I may be allowed to add that all methods hitherto proposed of calculating shot ranges seem to me too difficult for common use, and I believe what would really be a boon to the artilleryman is a book of trajectories drawn to scale. This might be accomplished very well by Mr. Bashforth's tables and methods in the hands of some one competent to use them, the simpler methods, as I think them, introduced by me, being also of some service. I trust this will be done when the resistance to shot moving with low velocities has been ascertained, as I hear it is to be, by a series of experiments under Mr. Bashforth's superintendence.

Allow me in conclusion to express my regret that I should seem to have been reviewing in a hostile spirit any part of the work done by Mr. Bashforth at Woolwich. I will only assure him that nothing could have been further from my thoughts than to do so. W. D. NIVEN

Trinity College, Cambridge, March 30

The Daylight Meteor of March 25

A CORRESPONDENT in NATURE described the falling of a daylight meteor on Monday, March 25. I have received information respecting this meteor from five persons who witnessed its fall.

Mr. McIntyre, who saw it from near Dunston-on-Tyne; Mr. Wood, banker, who saw it whilst leaving his residence at Benton, near Newcastle-on-Tyne; Mrs. Hopper, from Gosforth, one mile north of Newcastle; Mrs. Lupton, who saw it from a railway carriage at Brampton, near Carlisle; and Mr. W. Clarke, of Newburn, who saw it at Wallbottle, four miles west of Newcastle. All these observers agree in the following particulars:—1. That the meteor was visible at 10.20. 2. That it was very luminous with a white light slightly coloured. 3. That it fell at a slight inclination from E. to N., and reached the horizon at or near the north point. 4. That the weather was clear and the sun shone brightly at the time the meteor was visible. T. P. BARKAS

26, Archbold Terrace, Newcastle-on-Tyne

Meteor

ON the night of Tuesday, April 2, at about 7.55 o'clock, I was standing with two companions, facing the north, when we were surprised to observe the ground before us suddenly lighted up, and our three shadows sharply defined upon it. One of my friends exclaimed, "Why, there's the moon come out!" We turned round and beheld a wonderfully brilliant meteor descending almost perpendicularly from about 5° east of Betelgeux, in Orion, towards the most eastern of the three stars in the belt. Its course was slightly zig-zag, its colour yellow or orange, its apparent size about half the diameter of the full moon. It vanished noiselessly before reaching the belt, and left no visible remains. When we first saw it there appeared be a short trail of light behind it. About three minutes after its disappearance a rumbling sound was heard like distant thunder, from the same direction. Whether this was connected with the meteor I cannot tell. If so it would indicate a distance of about forty miles, and we ought to hear of this meteor from the neighbourhood of Warwick. F. T. MOTT

Birstal Hill, Leicester

[The same meteor was seen by several *Times* correspondents. It made its appearance in Ursa Major, and after remaining stationary for a second or two between Orion's Belt and Sirius, fell at a comparatively slow rate and in a direct line to the horizon. It was pear-like in shape, seemed three or four times larger than Jupiter, and was intensely bright. Its colour changed from a silvery white to a pale red as it approached the horizon, where it disappeared behind a cloud, leaving a long track of light behind it.]

To Entomologists

As I have undertaken the section "Arthropoda" for the "*Jahresbericht für Anatomie und Physiologie*, of Hoffmann and Schwalbe," and find some difficulty in obtaining English scientific journals (specially the entomological ones) here in Naples, will you permit me through your columns to request such of your readers as may have published papers on the *anatomy*, *ontogeny*, and *phylogeny*, of the *Hexapoda*, *Myriapoda*, *Arachnoidea*, *Protracheata*, *Poecilopoda*, and *Crustacea* in 1877, or intend to do so in 1878 and the following years, to be kind enough to forward me a copy of them, or at least to inform me of the fact? PAUL MAYER

Naples, Stazione Zoologica, March 31

GEOGRAPHICAL NOTES

ROYAL GEOGRAPHICAL SOCIETY MEDALS.—The Founder's Medal for 1878, of the Royal Geographical Society, has been awarded to Baron F. von Richthofen for his extensive travels and scientific explorations in China; also for his great work now in course of publication, in which the materials accumulated during his long journeys are elaborated with remarkable lucidity and completeness. The Patron's Medal has been given to Capt. Henry Trotter, R.E., for his services to geography, in having conducted the survey operations of the late Mission to Eastern Turkistan, under Sir Douglas Forsyth, which resulted in the connection of the Trigonometrical Survey of India with the Russian Surveys from Siberia, and for having further greatly improved the map of Central Asia. Mr. Stanley, being already a medallist, is disqualified from receiving a similar honour, but he has been elected an honorary corresponding member, and is to receive the thanks of the Council for his discoveries.

AFRICA.—With a view to facilitating the progress of the London Missionary Society's contemplated expedition from the East Coast of Africa to Lake Tanganyika, the Rev. Roger Price, who had had long experience of roads and waggons in South Africa, was despatched to Zanzibar in 1876, to make investigations respecting a new route and new mode of travelling into the interior. He made the experiment of using bullocks and waggons in the place of *pagazi*, and with so much success that it was resolved that the expedition should adopt that mode of conveyance for themselves and their goods, and a flourishing account of the new scheme was given before the Royal Geographical Society on February 26, 1877. Before the expedition arrived at Zanzibar in the summer of last year, Mr. Mackay, an agent of the Church Missionary Society, was reported to have cleared a road nearly, if not quite, as far as Mpwapwa, and it was supposed that the expedition would reach the Lake with great ease. Their hopes, however, have been grievously disappointed. The road has turned out to be no road at all, and most of the oxen have died from the effects of the climate. Mr. Price returned to England some little time back, convinced, we believe, of the present impracticability of his bullock-waggon scheme, and sad to relate, it has been found necessary to revert to the old *pagazi* system, the curse of African travel. By latest accounts the expedition had formed a camp at Kirasa, in Usugara, on the edge of the high plateau, and about forty miles east of Mpwapwa, and there they intend to remain till after the rainy season.—Lieut. J. B. Wathier has been appointed to join the Belgian expedition at Zanzibar, which recently lost two of its members, MM. Crespel and Maes. He has visited Dr. Nachtigall at Berlin, to obtain the advice of the experienced explorer, and left Brindisi for Zanzibar on the 5th inst. Dr. Nachtigall himself, as leader of the German expedition, is to start from St. Paul de Loanda, and it is hoped that the two expeditions may meet in the centre of Africa.

On the 5th inst. Lieut. de Semellé left Bordeaux for the purpose of setting out on his proposed journey across Africa from Senegambia. The Society of Algerine Catholic Missions has obtained from the Pope an authorisation to send two parties of priests into the interior of Africa; one, under the direction of Father Pascal, will establish a *vicariat apostolique* on the banks of Lake Tanganyika; the second party, whose head is said to be Father Livinzac, will establish a similar organisation in the region of the Nyanzas. The missions will be scientific as well as religious.

Arctic Exploration.—A wealthy Russian merchant M. Sibiriakoff has offered the sum of 12,000 roubles to the Committee of the Dutch Arctic Expedition, on condition that the Committee should order that the Siberian coasts be specially explored by the Expedition. The Committee has, however, refused the offer, on the one hand because it was considered undignified to accept foreign help for a purely national undertaking, and on the other, because the expedition has a specifically scientific and not a commercial object. This offer of M. Sibiriakoff seems unnecessary, seeing that the Siberian coast is likely to be explored this summer by Prof. Nordenskjöld in the *Vega*. We may remind our readers that this expedition sets out in the beginning of July, for the purpose of forcing the North-East Passage from Europe to Behring's Straits. Prof. Nordenskjöld has made a thorough study of the records of Russian exploration along the north coast of Siberia, and concludes that in early autumn the ice retires from the coast as a rule, leaving a comparatively clear waterway. Even should the immediate aim of the expedition not be accomplished, we may expect large additions to our knowledge of the hydrography, geology, and natural history of these regions, which, from a scientific point of view, have been comparatively unexplored. Prof. Nordenskjöld conjectures that a line of islands separates the Siberian from the strictly Polar Sea, of which we only know Wrangell Land and New Siberia; he will endeavour to verify this conjecture. The proposal has been made in the first Chamber of the Swedish Reichstag to grant the sum of 22,000 Swedish crowns for the Arctic Expedition projected by Lieut. Sandeberg, the costs of whose exploration in Lapland, to which we have already referred, were defrayed entirely by himself.

Cairo Geographical Society.—At an extraordinary meeting of this society on February 16 the question of its existence was discussed; it had become almost extinct from want of funds. It was proposed to join it to the Egyptian Institute, thereby much diminishing its working expenses, and putting it in an advantageous position for carrying on its work. We hope the scheme will be carried out, as the situation of the society places it in an unusually favourable position for carrying on the work of African exploration.

South America.—Advices from Valparaiso state that Commander Paget, of Her Majesty's ship *Penguin*, communicated to the captain of the port of Coquimbo that while passing through Messier's Channel, on January 10, he saw a volcano in eruption, situated E. ¼ S. (Mag.) of the southern extremity of Middle Island, English Narrows. It is supposed that this volcano is the cause of the subterranean noises heard by an exploring party from the corvette *Magallanes*, near Lake Santa Cruz, in the middle of December, and is the same as that believed to exist by the Argentine explorer Moreno. *Apropos* of the foregoing, says the *Timpos*, one of the most remarkable discoveries made by Chilian explorers is the complete disappearance of the Andes chain at the southern extremity of the continent. Messrs. Rodgers and Ibar crossed from Brunswick Peninsula, situated, according to the Argentines, to the east of the Andes, to the Pacific, arriving at a place called by Fitzroy the plains of Diana, without meeting with vestiges of the Cordillera. There are plains, more or less inclined, but only plains.

Ethnography of Russia.—As Supplement 54 to Petermann's *Mittheilungen*, Col. Rittich's valuable and elaborate treatise on the ethnography of Russia has just been published, with a large map, coloured with the greatest care, and showing with wonderful clearness the many elements which go to make up the Russian population.

The Yenissei.—To the April number of the *Geographical Magazine* Mr. Seebohm contributes a paper on the Valley of the Yenissei, embodying some of the results of his recent voyage to that river.

The Whang-ho.—In the same number is the first instalment of an exhaustive paper on this river, with special reference to its double delta, by Mr. Samuel Mossman.

Educational Voyage.—A voyage around the world, designed for students, is being arranged at Paris. It will last eleven months, over six months being devoted to various land excursions. Books, collections, &c., will be taken, and the entire programme will have instruction, rather than sight-seeing, in view. It is intended to depart on June 15.

Paris Geographical Society.—The January *Bulletin* of this Society contains the first part of an important inquiry into the medical geography of the West Coast of Africa, by Dr. H. Rey, and also the first instalment of a narrative of a journey in Cilicia in 1874 by MM. C. Favre and B. Mandrot. M. Nogueira gives a translation of a paper from the Portuguese on the South African river Cunene.

The Council of the Society of Geography has issued its list of candidates for the high offices of the society. It proposes to the members to elect Admiral La Roncière le Nourry, who has been voted six or seven times almost without opposition. But a number of independent members are proposing, in opposition, the nomination of the present Minister of Marine.

Depths of Lakes.—*The Bavarian Courier* publishes an interesting comparative statement of the depths of lakes. Amongst European lakes the Achensee, in the Tyrol, heads the list. At some points the depth of this lake amounts to 770 metres. The greatest depth of the lake of Constance is about 300 metres, that of the Chiemsee about 141 metres, and that of the Walchen- and Königssee, 188 metres. The measurements made about 1870 at the Dead Sea showed that at its deepest part the depth is 565 metres, but if we consider that the level of this lake is already 429 metres below the level of the Mediterranean, then we find that the total depression in the soil here amounts really to 994 metres. The Lake of Tiberias is extremely shallow in comparison; on its eastern part the average depth is only eight metres, while on the western side it lies between six and seven metres. In Lake Baikal depths have been found which for a lake are truly astonishing. In the upper part of the lake the depth is 3,027 metres (about the height of Mount Etna), but downwards the bottom constantly descends, and near the opposite bank the depth amounts to 3,766 metres. This depth far exceeds that of the Mediterranean Sea, which at its deepest part measures only 2,197 metres.

German Alpine Club.—The German and Austrian *Alpen Verein*, although comparatively young, has developed a most praiseworthy activity in a variety of directions. From the last general report we notice that it has a membership of nearly 7,000, and an annual income of 40,0[illegible] marks. The chief exertions are devoted to the erection of shelter huts in the Alps, and maintenance of communications over the passes. It is, however, rendering no slight service to the cause of geography, by the gradual preparation of elaborate maps of the German and Austrian Alps. At present it is engaged on a map of the Salzkammergut, on a scale of 1 : 100,000.

A LUNAR LANDSCAPE

MESSRS. GAMMON AND VAUGHAN, No. 28, Old Bond Street, have at present on view a picture in which the artist, Olafs Winkler, of Weimar, has endeavoured to represent a lunar landscape. Prof. C. Bruhns, of Leipzig, has assisted him in the parts of the treatment which are directly scientific.

The painter has not trusted all to his imagination. He has, to the best of his knowledge and ability, sought to stick rigidly to truth, and to paint a lunar landscape such as it would appear, so far as human observation has hitherto ascertained, to a human eye, were it at all possible for a man to be transplanted to the moon and observe through his earthly eyes, only for a moment, nature as she manifests herself on the surface of our satellite. From the merely artistic point of view the artist fears his task may be a thankless one, for since the moon has no atmosphere, there is neither aërial perspective nor diffusion of light, but it is precisely this point which should make our artist all the more interested in this unique production. The shadow of a body in the foreground will appear quite as black as the sky itself which closes the landscape like a flat steep wall, broken only by the quiet light of the stars. All lights appear equally strong at a distance and close at hand, and this also holds with the local colouring. In a word, there is wanting in the lunar landscape that which lends to our earth perspective, richness of tone, modulation, softness, and temper. It is our atmosphere we have to thank for most of the multitudinous coloured phenomena of the terrestrial landscape—phenomena which in our satellite are impossible. The sunlight falls upon the hills with blinding brightness, and cuts sharply across the deep black shadows. Its intensity rivals the electric light, and light effects of such a kind are far beyond the reach of our palettes. We must resort to some expedient to be able to introduce a medium between the extreme contrast of light and shade, a sort of half-tone, which, at the same time, must be the chief tone of the picture; this Herr Winkler has sought in the light of the earth, the true "earthshine."

The artist has chosen the time of sunset, and the region he has selected lies in the northern part of the moon. The spectator is supposed to be on the front slope of a mountain, the continuation of which in the background comes out as a closed ridge. At his feet one of the numerous *maria* spreads out, filled up with rills, circular hills, and large and small craters, stretching away to the distant mountain referred to. Before, us in the black sky, hangs the moon's moon, our earth. She sheds her pale, ash-coloured light over the rent, desolate, dead stone-fields. Only the highest points of the mountain-tops still glow in the light of the setting sun, no longer red, as here, but dazzlingly white, in consequence of the absence of atmospheric absorption. The earth is at the period of her course between Sagittarius and the Scorpion, Antares being nearly in the middle of the picture. Against his persuasion he has been compelled to make the milky way very weak, and the stars somewhat large in proportion to the earth.

Herr Winkler, in a paper read at the last meeting of the German Association, stated that his first impulse to undertake the picture was derived from Nasmyth and Carpenter's work on the moon.

Our only criticism of the picture refers to the colour of the earth and of the true earthshine. We doubt whether the earth is quite red enough, especially at the edges, and we doubt again whether, with the earth as ruddy as it is, the colour of the lunar landscape itself should not be rather more in harmony with it, as it is the true light source.

The picture is an admirable performance, and the science of it is so true that, as we hinted before, those of our artists who care to have a natural basis for their depiction of natural phenomena will learn much from such an attempt at dealing with a new order of things.

EDISON'S TALKING-MACHINE[1]

MR. THOMAS A. EDISON has recently invented an instrument which is undoubtedly the acoustic marvel of the century. It is called the "Speaking Phonograph," or, adopting the Indian idiom, one may aptly call it "*The Sound-Writer who Talks.*" Much curiosity has been expressed as to the workings of this instrument, so I purpose giving an account of it.

All talking-machines may be reduced to two types. That of Prof. Faber, of Vienna, is the most perfect example of one type; that of Mr. Edison is the only example of the other.

Faber worked at the source of articulate sounds, and built up an artificial organ of speech, whose parts, as nearly as possible, perform the same functions as corresponding organs in our vocal apparatus. A vibrating ivory reed, of variable pitch, forms its vocal chords. There is an oval cavity, whose size and shape can be rapidly changed by depressing the keys on a key-board. A rubber tongue and lips make the consonants; a little windmill, turning in its throat, rolls the letter *r*, and a tube is attached to its nose when it speaks French. This is the anatomy of this really wonderful piece of mechanism.

Faber attacked the problem on its physiological side. Quite differently works Mr. Edison: he attacks the problem, not at the source of origin of the vibrations which make articulate speech, but, considering these vibrations as already made, it matters not how, he makes these vibrations impress themselves on a sheet of metallic foil, and then reproduces from these impressions the sonorous vibrations which made them.

Faber solved the problem by reproducing the mechanical *causes* of the vibrations making voice and speech; Edison solved it by obtaining the mechanical *effects* of these vibrations. Faber reproduced the movements of our vocal organs; Edison reproduced the motions which the drum-skin of the ear has when this organ is acted on by the vibrations *caused* by the movements of the vocal organs.

Figs. 1 and 2 will render intelligible the construction of Mr. Edison's machine. A cylinder, F, turns on an axle which passes through the two standards, A and B. On one end of this axle is the crank, D; on the other the fly-wheel, E. The portion of this axle to the right of the cylinder has a screw-thread cut on it, which, working in a nut, A, causes the cylinder to move laterally when the crank is turned. On the surface of the cylinder is scored the same thread as on its axle. At F (shown in one-half scale in Fig. 2) is a plate of iron, A, about $\frac{1}{100}$ of an inch thick. This plate can be moved toward and from the cylinder by pushing in or pulling out the lever H G, which turns in an horizontal plane around the pin I.

The under side of this thin iron plate, A (Fig. 2), presses against short pieces of rubber tubing, X and X, which lie between the plate and a spring attached to E. The end of this spring carries a rounded steel point, P, which enters slightly between the threads scored on the cylinder C. The distance of this point, P, from the cylinder is regulated by a set-screw, S, against which abuts the lever, H G. Over the iron plate, A, is a disc of vulcanite, B B, with a hole in its centre. The under side of this disc nearly touches the plate A. Its upper surface is cut into a shallow, funnel-shaped cavity, leading to the opening in its centre.

---

[1] The figures in this article are taken from "Sound, a Series of Simple, Entertaining, and Inexpensive Experiments in the Phenomena of Sound, for the Use of Students of every Age." By Alfred M. Mayer. Vol. ii. of "Experimental Science Series for Beginners." (Now in press and soon to be published by D. Appleton and Co.)

To operate this machine, we first neatly coat the cylinder with a sheet of foil, made to adhere by coating the edges with shellac varnish, then we bring the point, P, to bear against this foil, so that, on turning the cylinder, it makes a depressed line, or furrow. The mouth is now placed close to the opening in the vulcanite disc, B B, and *the metal plate is talked to* while the cylinder is revolved with a uniform motion.

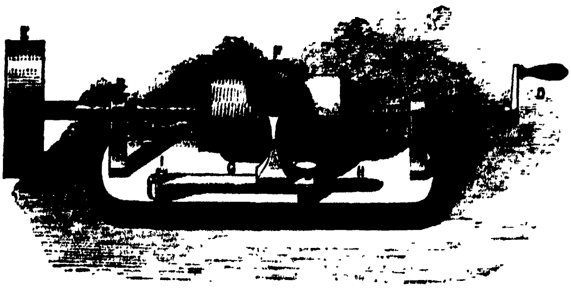


FIG. 1.—Edison's Talking-Phonograph.

The plate, A, vibrates to the voice, and the point, P, indents the foil, impressing in it the varying numbers, amplitudes, and durations of these vibrations. If the vibrations given by the voice are those causing simple sounds, and are of a uniform, regular character, then similar, regular, undulating depressions are made in the foil. If the vibrations are those causing complex and irregular sounds (like those of the voice in speaking), then, similarly, the depressions made in the foil are complex, having profiles like the curve, B, in Fig. 3. Thus the yielding and inelastic foil receives and *retains* the mechanical impressions of these vibrations with all their minute and subtile characteristics.

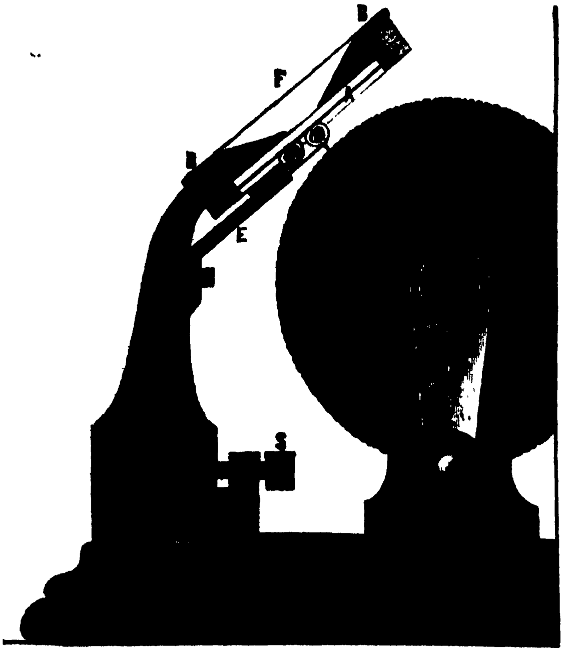

FIG. 2.

The permanent impressions of the vibrations of the voice are now made. It remains *to obtain from these impressions the aerial vibrations which made them.* Nothing is simpler. The plate A, with its point, P, is moved away from the cylinder by pulling toward you the lever, H G. Then the motion of the cylinder is reversed till you have brought opposite to the point P the beginning of the series of impressions which it has made on the foil. Now bring the point up to the cylinder; place against the vulcanite plate, B B, a large cone of paper or tin to re-enforce the sounds, and then steadily turn the crank, D. The elevations and depressions which have been made by the point, P, now pass under this point, and in so doing they cause it and the thin iron plate to make over again the precise vibrations which animated them when they made these impressions under the action of the voice. The consequence of this is, that the iron plate gives out the vibrations which previously fell upon it, and it *talks back to you what you said to it.*

By the following method we have just obtained several magnified traces on smoked glass of the contour, or profile, of the elevations and depressions made in the foil by the sonorous vibrations. On the under side of the shorter arm of a delicate lever is a point, made as nearly as possible like the point, P, under the thin iron plate, A. Cemented to the end of the longer arm of this lever is a pointed slip of thin copper-foil, which just touched the vertical surface of a smoked-glass plate. The point on the short arm of the lever rested in the furrow in which are the depressions and elevations made in the foil on the cylinder. Rotating the cylinder with a slow and uniform motion, while the plate of glass was slid along, the point of copper-foil scraped the lamp-black off the smoked-glass plate and traced on it the magnified profile of the depressions and elevations in the foil on the cylinder. I say expressly *elevations* as well as depressions in the foil, because, when the plate vibrates outward, the furrow in the foil often entirely disappears, and is always lessened in its depth by this outward motion of the point. One who has never made a special investigation of the character of the impressions on the phonograph, and forms his opinion from their appearance to his eye, might state that they are simply dots and dashes, like the marks on the filet of a Morse instrument

Another method of obtaining the profile of the impressions on the foil is to back it with an easily-fusible substance, and then, cutting through the middle of the furrows, we obtain a section, in which the edge of the foil presents to us the form of the elevations and depressions]

The instrument has been so short a time in my possession, that I have not had the leisure to make on it the careful and extended series of experiments which it deserves. I have, however, obtained several traces, and I have especially studied the characters of the trace of the sound of *bat.* As far as the few experiments warrant an expression of opinion, it seems that the profile of the impressions made on the phonograph and the contours of the flames of König, when vibrated by the same compound sound, bear a close resemblance.

In Fig. 3 we give on line A the appearance to the eye of the impressions on the foil, when the sound of *a* in *bat* is sung against the iron plate of the phonograph. B is the magnified profile of these impressions on the smoked glass obtained as described above. C gives the appearance of König's flame when the same sound is sung quite close to its membrane. I say expressly *quite close* to its membrane, for the form of the trace obtained from a point attached to a membrane vibrating under the influence of a compound sound depends on the *distance* of the source of the sound from the membrane, and the same compound sound will form an infinite number of different traces as we gradually increase the distance of its place of origin from the membrane; for, as you increase this distance, the waves of the components of the compound sound are made to strike on the membrane at different periods of their swings.

For example, if the compound sound is formed of six harmonics, the removal of the source of the sonorous vibrations, from the membrane to a distance equal to $\frac{1}{4}$ of a wave-length of the first harmonic, will remove the second, third, fourth, fifth, and sixth harmonics to distances from the membrane equal respectively to $\frac{1}{2}$, $\frac{3}{4}$, 1, $1\frac{1}{4}$, and $1\frac{1}{2}$ wave-lengths. The consequence evidently is, that the resultant wave-form is entirely changed by this motion of the source of the sound, though the sonorous sensation of the compound sound remains unchanged.

The above facts are readily proved experimentally by sending a constant compound sound into the cone of König's apparatus, while we gradually lengthen the tube between the cone and the membrane next to the flame. This is best done by the intervention of one tube sliding in another, like a trombone. These experiments I have recently made with entire success, and they explain the discussions which have arisen between different observers as to the composition of vocal and other composite sound, as analysed by means of König's vibrating flames.

These facts also show how futile it is for any one to hope to be able to *read* the impressions and traces of phonographs, for these traces will vary, not alone with the quality of the voices, but also with the differently-related times of starting of the harmonics of these voices, and with the different relative intensities of these harmonics.

It is necessary to give to the cylinder a very regular motion of rotation while it receives and reproduces the vibrations made in singing; for even slight irregularities in the velocity of the cylinder destroy the accuracy of the musical intervals, and cause the phonograph to sing falsetto. Even the reproducing of speech is greatly improved by rotating the cylinder by mechanism which gives it uniformity of motion. If you make the machine talk by giving it a more rapid rotation than it had when you spoke to it, the pitch of its voice is raised; and by varying the velocity of the cylinder the machine may be made to speak the same sentence in a very bass voice, or in a voice of a pitch so high that its sounds are really elfish and entirely unnatural.

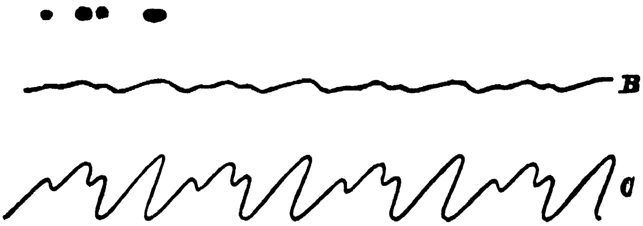

FIG. 3.

Recent experiments seem to show that the nearer the diaphragm A approaches to the construction of the drum-skin of the human ear by "damping" it, as the hammer-bone does the latter, the better does it record and repeat the sonorous vibrations; for the motion of a membrane thus damped is ruled alone by the aërial vibrations falling on it.

Mr. Edison has just sent me the following notes of the results of recent experiments:—

"That the size of the hole through which you speak has a great deal to do with the articulation. When words are spoken against the whole diaphragm, the hissing sounds, as in *shall, fleece, last*, are lost; whereas, by the use of a small hole provided with sharp edges, these words are reinforced and recorded. Also, teeth around the edge of a slot, instead of a round hole, give the hissing consonants clearer.

"That the best reading is obtained when the mouth-piece, B F B (Fig. 2), is covered with several thicknesses of cloth, so that the snapping noise on the foil is rendered less audible.

"I send you a sheet of copper-foil upon which I made records in Ansonia, Connecticut, that could be read 275 feet in the open air, and perhaps farther, if it had been tried."

Mr. Edison also states that impressions of sonorous vibrations have been made on a cylinder of soft Norway iron, and from these impressions have been reproduced the sonorous vibrations which made them.

ALFRED M. MAYER

THE OLD RED SANDSTONE OF WESTERN EUROPE[1]

PART I.

IN a historical introduction the author gives an outline of the progress of research into the history of the Old Red Sandstone of the British Area. This system is at present regarded as composed of three sub-divisions, Lower, Middle, and Upper, each characterised by a distinct suite of organic remains. From the absence of unequivocally marine fossils and from lithological characters, it has been inferred by Mr. Godwin Austen, Prof. Ramsay, Prof. Rupert Jones, as well as other observers, and is now very generally admitted that the Old Red Sandstone, as distinguished from the "Devonian" rocks, probably originated in inland sheets of water. The object of the present memoir was to endeavour to trace out in that geological system of deposits the changes of physical geography which took place over Western Europe during the interval between the close of the Upper Silurian and the beginning of the Carboniferous period.

After a sketch of the probable conditions of the region previous to the commencement of the Old Red Sandstone, the author proceeds to show how the shallowing Silurian sea was converted here and there into *salinas* or inland seas, by a series of subterranean movements which have left their indelible traces upon the upturned Silurian rocks. He divides his memoir into two parts, the first dealing with the Lower and the second with the Upper Old Red Sandstone. The present paper deals only with a portion of the first of these sections. It traces out the limits of the different basins in which the Old Red Sandstone of the British Islands were deposited, and for the sake of convenience as well as briefness of reference, proposes short geographical names for these basins, which are arranged as follows:—

---

[1] Abstract of paper by Prof. Geikie, F.R.S., read before the Royal Society of Edinburgh on April 1, 1878.

Area of the Basins.	Short reference names proposed to be applied to them.
1. The Old Red Sandstone tracts of the north of Scotland, embracing the region of the Moray Firth, Caithness, the Orkney Islands, the mainland of Shetland, and perhaps part of the south-western coast of Norway.	Lake Orcadie.
2. The central valley of Scotland between the Highlands on the north and the Silurian uplands on the south, including the basin of the Firth of Clyde, and ranging across the north of Ireland to the high grounds of Donegal.	Lake Caledonia.
3. A portion of the south-east of Scotland and north of England extending from near St. Abb's Head to the head of Liddesdale, and including the area of the Cheviot Hills.	Lake Cheviot.
4. A district in the north of Argyllshire extending from the mouth of the Sound of Mull to Loch Awe, and perhaps up into the southern part of the Great Glen.	Lake Lorne.
5. The Old Red Sandstone region of Wales and the border counties of England, bounded on the north and west by the older palæozoic hills, the eastern and southern limits being unknown.	The Welsh Lake.

Lake Orcadie.—After describing the limits of this basin, and giving a sketch of the labours of previous observers in the Old Red Sandstone tracts of the north of Scotland, the author proceeds to examine the evidence for the threefold arrangement of the Old Red Sandstone proposed by Murchison. He shows that nowhere are the three groups, Lower, Middle, and Upper, found in consecutive order; that this so-called "Middle" division occurs only in the north of Scotland, where it lies unconformably upon the older palæozoic rocks, and is itself unconformably overlaid by the Upper Old Red Sandstone, thus occupying a position exactly similar to that of the Lower Old Red Sandstone on the southern side of the Highlands. He further points out that while some species of fishes are common to the Old Red Sandstone on the two sides of the Highland barrier, the lithological differences between the deposits of the two areas are so great as to make it evident that the rocks were laid down in distinct basins and consequently that the fauna of each basin might be expected to be more or less peculiar, as in many analogous cases at the present day. As evidence that adjacent areas in the time of the Lower Old Red Sandstone were strongly marked off from each other in their faunas, reference is made to the contrast between the fishes and crustaceans of the Welsh region and those of Lanarkshire and Forfarshire, not a single species being common to the two countries though some of the genera are. Reasons are then given why the argument used by Murchison from the occurrence of many of the Scottish ichthyolites in Russia could not be regarded as establishing the existence of a "Middle" division of the Old Red Sandstone.

The conclusion arrived at by the author is that the Caithness flags or "Middle Old Red Sandstone" are probably the general equivalents of the Lower Old Red Sandstone of other regions, and that this system consists in Britain of two well-marked divisions only—a Lower, which graduates in some places into the Upper Silurian rocks and is separated by an unconformability from an Upper which in many districts passes up into the base of the Carboniferous system.

The various districts into which the area embraced under the term Lake Orcadie may be divided are then described *seriatim*. The detailed structure of Caithness has been worked out by the author (partly with the cooperation of his colleagues in the Geological Survey, Mr. B. N. Peach and Mr. John Horne) as affording the most complete sections of the Old Red Sandstone in the North of Scotland. Arranged in descending order, the various stratigraphical zones stand as in the subjoined table:—

	Thickness in feet.
9. John O'Groats Red Sandstone, Flagstones, and impure Limestones and Shales	2000
8. Huna Flagstones, Shales, and Limestones ...	1000
7. Gill's Bay Red Sandstones	400
6. Thurso or northern group of Flagstones, Shales, and Limestones	5000
5. Wick or eastern group of Flagstones, Shales, and Limestones passing down into Red Shales and Sandstones	5000
4. Dull Red Sandstones, Red Shales, and fine Conglomerates...	2000
3. Brecciated Conglomerates	300
2. Badbea Red Sandstones and Shales or Clays..	450
1. Coarse basement Conglomerates	50
	16,200 ft.

From the four lowest sub-divisions no fossils have yet been obtained. The flagstones have yielded to Mr. C. W. Peach, and other observers many land plants (some of which resemble forms described by Dawson from the Gaspé sandstones) as well as *Estheria membranacea*, *Pterygotus*, sp., and many ichthyolites. Availing himself of the list of localities furnished to him by Mr. Peach (to whom he cordially acknowledges his obligations) with the species of fish found at each, the author has constructed a table of the vertical distribution of the fossil fishes in Caithness. Some of the species range through almost the entire succession of beds. Some, however, are either peculiar to or very characteristic of one sub-division. Thus *Osteolepis arenatus* and *Dipterus Valenciennesi*, are not noted except from the group No. 5. In the Thurso and the higher flagstones (Nos. 5, 8, and 9) *Acanthodes*, *Parexus*, *Cheiracanthus*, *Diplacanthus*, *Pterichthys*, *Tristichopterus*, and *Holoptychius*—genera absent from the Wick beds—are found in greater or less abundance. These strata are further marked by peculiar species of genera which likewise occur among the older flagstones, as *Coccosteus pusillus* and *Osteolepis microlepidotus*.

The Orkney Islands are assigned to the higher subdivisions of the flagstone series, the protruding ridge of granite and gneiss which rises at Stromness and Gremsa being merely an indication of the irregular surface, on which the deposits of Lake Orcadie were accumulated, and of the slow progressive subsidence of the area. The fossils, for which these islands have long been famous, include most of those of the upper groups of Caithness, with the addition of others which have been regarded as distinct. In the determination of these fossils much skill is required to discriminate between the accidental differences of aspect resulting from the condition of fossilisation. The Orkney fishes, for instance, are preserved as black jet-like impressions which, often very perfect when first removed from the quarry, are apt to scale off, leaving in each case only an amorphous layer which, though it retains the contour of the fish, shows little or no trace of structure. On the shores of the Moray Firth, on the other hand, the organisms have been inclosed within calcareous nodules; their colours are sometimes brilliant, and their scales, plates, fins, and bones, are often admirably preserved and remain unchanged in the Museum. Want of experience in these different modes of preservation may have led to a reduplication of species, especially in the case of the Orkney and Moray Firth fishes. Among the most interesting Orkney fossils is a portion of a *Pterygotus* (recognised by Dr. H. Woodward), now in the British Museum. The occurrence there of this characteristically Upper Silurian and Lower Old Red Sandstone genus supports the view contended for in this paper as to the true horizon of the Orkney and Caithness flagstones.

The Shetland Islands contain a portion of the shore-line of Lake Orcadie with its conglomerates and sandstones and the flagstones and shales of deeper water. Among these strata the Caithness *Estheria* occurs, with abundant stems and roots of large calamite-like plants with well-marked flutings but without observable joints. Some ichthyolites of the Caithness type are said to have been found in Bressay. The general lithological characters are quite those of the sandy parts of the Orkney and Caithness groups. On the west side of the mainland of Shetland interesting evidence occurs to show the existence of volcanic action contemporaneous with the accumulation of the Old Red Sandstone. Beds of amygdaloidal lavas and bands of tuff occur among the sandstones, the whole being pierced by masses of pink felsite.

The south-western and southern margin of this great northern basin of the Old Red Sandstone can still be traced nearly continuously from the confines of Caithness to the borders of Aberdeenshire, its position being marked by a zone of littoral conglomerates. Beyond the edge of that zone, however, there occur some interesting outliers which in some cases may represent long fjord-like indentations of the coast line; in others may mark what were really independent basins lying at the base of the Grampian Mountains. The author points out that probably most of the difficulty which has hitherto been experienced in understanding the sequence of beds along the southern shores of the Moray Firth and their parallelism with those of Caithness and Orkney is not to be attributed to the amount of detritus covering the country, but rather to the fact which has not heretofore been observed that the Upper Old Red Sandstone with *Holoptychius* and *Pterichthys major* really overlap unconformably upon the older nodular clays and conglomerates with *Coccosteus*, *Cheirolepis*, &c. This relation could be satisfactorily determined in Morayshire, and was now being worked out by Mr. John Horne in the course of the Geological Survey. The author traces in great detail from the Spey into Sutherlandshire, the development of the lower sandstone conglomerates and clays, which have been regarded as equivalents of the Caithness flagstones. He thinks that in no sense can this comparatively thin group of rocks (seldom 1,400 feet in depth) be regarded as a mere southward attenuation of the great Caithness series, as suggested by Murchison, for that neither lithologically nor palæontologically can that view be sustained. He has been led to the conclusion that the whole of these rocks from the borders of Sutherlandshire to those of Aberdeenshire represent only the higher portions of the great Caithness series, and that they were formed during a gradual depression of the ancient high grounds whereby the waters of Lake Orcadie were allowed to creep southward over the descending land. This movement is indicated by the character of the strata, and that it took place about the time of deposit of the later flagstones of Caithness is shown by the occurrence of the fossils of that division in the nodules, flags, and clays of the Moray Firth region, while those of the Lower division are absent.

Allusion is likewise made to the discovery of two localities where contemporaneous volcanic action has recently been observed in the Moray Firth area, the whole of the basin of Lake Orcadie being otherwise remarkably free from any trace of such action except on the northern margin in Shetland. The history of the area embraced by Lake Caledonia will form the subject of the next paper.

NOTES

We regret to have to announce the death of Dr. F. Brüggemann. Dr. Brüggeman was a native of Bremen and studied at Jena, where he was for several years assistant to Prof. Haeckel. His earliest publications were on entomological subjects, but later he published an account of the Amphibians and Reptiles of Bremen. He was especially interested in ornithology, and amongst other papers on this subject published two on the Birds of South-Eastern and Central Borneo (*Abhand. d. naturw. Vereins zu Bremen*, Bd. v. u. vi.). On the recommendation of Prof. Haeckel, Dr. Brüggemann was engaged last year by Dr. Günther to arrange and catalogue the collection of corals in the British Museum. Whilst in the midst of this undertaking he died suddenly at his lodgings on the night of Saturday last of hæmorrhage from the lungs. He had already named 1,500 species of corals in the collection, and had published two papers on undescribed forms in the *Annals and Magazine of Natural History*. He had in hand a revised list of all species of recent corals hitherto described, which was in an advanced state and which he had intended to have published. He was of an extremely amiable disposition and his loss is deeply regretted in London by the staff of the British Museum and other naturalists with whom he was acquainted. He was under thirty years of age at the time of his death.

On Thursday last the members of the General Council summoned to deliberate upon the improvements required in the organisation of the Paris Observatory waited upon M. Bardoux, the Minister of Public Instruction. They insisted upon the necessity of continuing the existing connection between astronomy and meteorology in accordance with the principles established by M. Leverrier himself, and developed the reasons which had led the majority to pass a resolution in favour of that system. A number of eminent scientific men had interviews with M. Bardoux, and have made a strong impression upon his mind. M. Bardoux has ordered all the letters from a number of departmental meteorological commissions to be summarised, and it has been found that not a single one has urged the disconnection of the two departments. We are in a position to state that according to every probability, during the present month, the Academy of Sciences and the new Council of the Observatory will be summoned to present each two candidates, between whom the Minister will exert his right of selection according to the provisions of the newly-published decree.

Captain Feilden, R.A., naturalist to the late British Expedition to the Arctic Regions, and Mr. De Rance, of H.M. Geological Survey, are announced to read a paper on the Geology of the Northern Lands visited, at the next meeting of the Geological Society of London, at which Mr. Etheridge will present a detailed report of the palæontology of the same area. We understand that the British Museum will probably be the destination of the very numerous collection of geological specimens made by Capt. Feilden, Dr. Coppinger, and other officers of the expedition.

M. Belgrand, Director of the Paris Sewers and Waterworks, died suddenly on the 8th inst. in his sixty-eighth year. To him Paris owes its network of sewers and its supply of water from the Dhuys, the Vanne, and the Somme Soude. He also devised the system of hydrological observations, by which floods are foreseen. As a connoisseur of water he is said to have had no rival.

It is stated that Prof. H. J. S. Smith, F.R.S., is to be a candidate for the representation of Oxford University in Parliament.

The coloured spherules discovered by M. Hannover in the cones of the retina of many birds are known to have three colours: a yellowish green, an orange yellow, and an intense ruby red. Lately, M. Capranica affirmed the identity of these different colouring matters and their close relation to visual red and the widely expanded lutein (found in the yolk of egg, adipose tissue, corpora lutea, the ovary of mammalia, &c.), and he cited various reactions as proving this relation. M. Kuhne has lately, in the *Centralblatt für die Medicin. Wiss.*, opposed this view; he has succeeded easily in isolating the three colouring matters after they were freed from fat, and he affirms that as regards spectroscopic behaviour, reaction, and solubility, they may be clearly distinguished.

THE French Academy had proposed for the prize of eloquence in 1877 the *éloge* of Buffon, the celebrated naturalist, and not less than seventeen memoirs were presented. Two were found so excellent that in opposition to the traditions of the Academy, they were declared *ex æquo*, as having obtained the premium. When the sealed envelopes containing the names of the authors were opened, it was found that one of them had died before he had quite revised his work. The name of this posthumous laureate is M. Narcisse Michaud. M. Dumas has written a letter of sympathy and regret to the family in the name of the Academy.

M. DE WATTEVILLE, one of the chief secretaries of the French Minister of Public Instruction, has lately submitted a plan for the formation of a large scientific committee in Paris, which shall stand in direct communication with all existing learned societies. The project will be put into execution during the present month, and M. Bardoux, the Minister of Public Instruction, will be the first president of the committee.

ON April 4 was held at the Tuileries a meeting of the several committees which had been appointed in order to organise the series of congresses intended to take place in Paris during the Universal Exhibition. After having returned thanks to his numerous subordinates for their exertions, the Minister for Public Works read a list of eleven congresses which are completely organised, viz.:—1. Agriculture. 2. Metrical and monetary, for the adoption of a universal system. 3. Special congress for determining a universal measure of threads of every description used in textile fabrics. 4. For the protection of literary, artistic, and industrial property, patents, &c., &c. 5. For provident institutions, life, fire, agriculture, &c., insurances. 6. Philological. 7. A congress inaugurated by European economists. 8. Meteorological. 9. The French Alpine Club will call a congress of every similar institution. 10. Public hygiene. 11. A congress for the international regulation of measures against the propagation of epizootics. Other congresses are in preparation. The several regulations will be published very shortly, mentioning the dates, the space of time allotted to them, the several programmes, the places of meeting, the conditions of admission, and the composition of initiative commissions.

HERR ACHENBACH, the Prussian Minister of Commerce, has lately issued an order that during the Paris Exhibition arrangements shall be made at the Berlin School of Mines to put at the service of those desiring to study the mineral wealth of the kingdom, all possible cartographical and literary requisites, as well as information as to the best means of reaching all points of interest in the mining regions; this disposition is made more especially for the benefit of American scientific visitors in recognition of the courtesies extended by them in this direction two years ago.

A GUIDE for the approaching Exhibition at Paris has just been published under the title "Guide de l'Exposition Universelle et de la Ville de Paris." (Paris: Bureau de la Publicité.) It contains no less than fifty-four maps and plans.

THE Institute of Naval Architects commences its annual session to-day; the meetings will be continued to-morrow and Saturday. A large number of papers on subjects of great importance are down for reading.

THE agents of the Paris Acclimatisation Society are engaged in organising, at Marseilles, a zoological garden which will be considered as an annexe to the Parisian establishment. A certain number of animals have already arrived but have not yet been placed in the cages which are being built for them.

A PAPER on "State Aid to Music at Home and Abroad" was read by Mr. Alan S. Cole, at the Society of Arts on Wednesday evening, March 27. Allusion was made to the constitution of foreign Conservatoires, which, to a considerable extent, depend upon the support given to them by the governments of the countries in which they are established. Government support gives an element of stability to these foreign Conservatoires, and Mr Cole endeavoured to show that in the United Kingdom there is an absence of stability in respect of the different music schools which exist. Our academies and schools of music have been founded by private enterprise, and their existence, depending upon the fluctuations of subscriptions and amateur fee-paying students, seems to have no guarantee of permanence. In regard to freely established classes for promoting science and art, the prospect of their becoming permanent is assisted by the offer of national payments for ascertained results of instruction. In elementary day schools the education department makes a payment of one shilling per child who attends a school where singing is taught. These shilling payments amount to 96,000*l*. a year. As, however, the Inspector of Music, Mr. John Hullah, reports that the musical proficiency of the children is bad, it may be inferred that not only is the instruction of the children in music bad, but the payment also of so large a sum as 96,000*l*. per annum is of little use in securing for national benefit an adequate return. The supply of duly qualified teachers in the art and science of music may probably tend to diminish the disproportion between the annual expenditure and the insufficient return of results in musical instruction. Accepting the general features common to Conservatoires abroad as the outlines for similar institutions at home, Mr. Cole called attention to the Royal Academy of Music and to the New National Training School for Music at Kensington. The Royal Academy is not a Conservatoire according to the definition given. The constitution of the National Training School is similar to that of the chief Conservatoires. The tendency of individual or private enterprise seems to direct itself towards the training of singers and performers; and it was stated that the Kensington School was at present training nearly a hundred scholars of this class. The duty of the Government is to provide qualified teachers, the results of whose instruction shall be of value to the country at large, and therefore properly to be paid for out of the exchequer. The form of State aid which it was suggested might be given was the payment of the fees of instruction of a certain number of students whose aim is to be teachers in elementary schools, in local classes, and music schools throughout the country. Such payment of fees would be made to that academy or training school whose proved methods of instruction seemed to be the best, and the work promoted by this kind of State aid would not compete with that part of national culture which is at present dependent upon the support given according to the whims of the givers, and therefore of an uncertain, spasmodic, unbusiness-like character.

M. CAZIN, the eminent French physicist, whose premature death we noticed a few months since, left a manuscript on Spectrum Analysis. This has just been published by Gauthier Villars in his "Actualités Scientifiques."

THE Annual Meeting of the Cumberland Association for the Advancement of Literature and Science will be held at Cockermouth on Easter Monday and Tuesday. A varied and interesting programme is arranged for the two days, one of the items being a lecture by Sir George Airy on "The Probable Condition of the Interior of the Earth."

For Easter Monday and following day the Geologists' Association have arranged what promises to be an interesting excursion to Chipping Norton. Provincial field societies are now also issuing programmes of their summer excursions; the Manchester Field Naturalists and the Leeds Naturalists have sent us well-arranged programmes of this kind.

Excavations in the neighbourhood of Merten, in Lorraine, have uncovered the remains of an old Roman temple, and brought to light a variety of weapons, busts, coins, &c. The indications all point to the existence of a large settlement here under the Roman rule, and arrangements have been made for a series of widely extended excavations.

The archæologists of Rome are busied over the latest discovery, the uncovering of a cellar containing a thousand vessels for various commercial purposes, two hundred of which are covered with inscriptions throwing no small light on the business terms of the ancient Romans.

In the course of a report, which has just been published by order of the Inspector-General of Maritime Customs in China, Dr. F. Wong gives us some curious particulars respecting a strange remedial agent employed by the Chinese in cases of *Cynanche Tonsillaris*. The disease they term *Ngo-hou*, or "Goose-throat," and the remedy in question is called *Hou-tsao*, a soft stone not unlike biliary calculus in appearance. It is expensive, being worth twenty times its weight in silver, and is said to come from Siam. Twenty or thirty grains of this in powder, taken in water, is thought to be very efficacious. Dr. Wong mentions having seen a case where this remedy was given, and where it certainly appeared effective, after gargles and astringents had been applied in vain. The specimens of the stone which have come under his notice appear like animal concretions, and are of various sizes, some being smaller than pigeons' eggs, while others are as large as hens' eggs. The story goes that, when a monkey is wounded, the animal, from its natural instinct, picks out the proper medicinal herbs, masticates and applies them to the wound, so that successive layers are in this way laid on so as to form a mass. In time the wound heals, and the lump of dried herbs falls off; it is then picked up by the Siamese, found by them to possess peculiar virtues, and sent in small quantities to China as a drug.

News from Berlin states that Prof. Mommsen has again started upon a scientific expedition to the south of Italy, from which he intends to return to Berlin at the end of May.

In the south of France no rain or snow has fallen since the beginning of the winter, and the prevailing drought resulting from this peculiar absence of atmospheric moisture has well-nigh assumed the proportions of a real catastrophe. The authorities have been obliged to take in hand the distribution of drinking water to the inhabitants. Between Marseilles and the Italian frontier certain railway stations are completely without water, and waggon-cisterns had to be constructed which are kept filled by water brought by train. The soil in the district is so hard that all agricultural work is impossible, and the crops are, of course, in a most miserable condition.

From Leipzig and its vicinity heavy rains are reported causing severe inundations in that neighbourhood.

Dr. A. Hartmann describes in the *Proceedings* of the Berlin Physiological Society for the present year, a new application of the telephone for the purpose of testing the hearing. It rests upon the fact that when the magnet of the receiving instrument is excited by a galvanic stream, the intensity of the tone transmitted can be altered at will by the introduction of various resistances or of Du Bois-Reymond's compensator into the circuit. By this means it is easy to measure comparatively in different persons the limits of hearing, by applying the telephone to the ear, and noticing the amount of resistance necessary in order to extinguish the same sound.

The American Chemical Society closes its second year with a membership of 300. Its *Transactions*, instead of appearing at irregular intervals, are to be published twice a month, and efforts are being made to concentrate in them all that America produces in the line of chemical research. The Society has chosen Prof. Johnson, the familiar authority on agricultural chemistry, for its president during 1878, and has elected to honorary membership Professors Frankland and Williamson, of London, Bunsen and Wohler of Germany, Berthelot of Paris, Boutlerow of St. Petersburg, and Cannizzaro of Rome.

An earthquake was felt at Liesthal, in the canton of Bâle during the night of March 28-29. This phenomenon was probably connected with another commotion which was registered at Strasburg Observatory by Winnecke, and was observed on March 29 at 8h. 52m. 27s. in the morning. The duration of the commotion was only ⅓s., and would have escaped notice if a registering apparatus had not been kept at the observatory. A violent earthquake was felt at Kaltenbrunn, in the Kaunser Valley (Tyrol) on March 16 at 5 A.M.

Mr. A. O. Thorlacius, the observer for the Scottish Meteorological Society at Stykkisholm, in the north-west of Iceland, reports the occurrence, on March 4, of the severest thunderstorm ever experienced in that part of Iceland. Thunder and lightning continued without interruption from 5.30 A.M. to 8 A.M., accompanied at intervals with rain and hail. For the past thirty-three years, during which Mr. Thorlacius has observed, nearly all the thunderstorms have occurred during the winter months. At 7 A.M. a very fine meteor passed over the village of Stykkisholm and exploded into innumerable fragments over the harbour, unaccompanied, however, with any audible report, and shortly after another fine meteor passed over the village and disappeared without being observed to explode. It is added that this is the first time such meteors have been observed by any one at Stykkisholm.

With regard to the fact stated by M. Forel, that frequently during distinct shocks of earthquake, the lakes show neither waves nor *seiches*, while at other times shocks produce large movements, M. De Rossi writes to *La Nature*, from Rome, that the lakes probably act according to the law of pendulums. Thus in Italy shocks of earthquake have frequently occurred without the pendulum seismograph showing any sign of movement, whereas, again, the pendulum may swing violently without the shock being perceived by any one. M. De Rossi has, with others, experienced a distinct shock of earthquake, and on immediately examining with a microscope eight pendulums of different lengths, could not detect the slightest motion. The fact evidently depends, he says, on the relation between the length of the pendulum and the rapidity of the earth-vibrations. When the seismic wave is *synchronous* with the natural oscillation of the pendulum, the latter enters into motion; when it is *dissynchronous*, the pendulum refuses to move.

It will be seen from our advertising columns, that pending the erection of the permanent buildings of the Channel Islands' Zoological Station, St. Helier's, Jersey, arrangements have been made for placing private rooms with tables and apparatus at the disposal of a limited number of naturalists and students, with every assistance in obtaining subjects for investigation.

The additions to the Zoological Society's Gardens during the past week include two Persian Gazelles (*Gazella subgutturosa*) from Persia, presented by Mr. R. W. Inglis; a Macaque

Monkey (*Macacus cynomolgus*) from India, presented by Mr. Francis Pym; a Common Squirrel (*Sciurus vulgaris*), European, presented by Madame Hante; a Vulpine Phalanger (*Phalangista vulpina*) from Australia, presented by Capt. F. Ayling; a Pudu Deer (*Cervus humilis*), a Naked-eared Deer (*Cervus gymnotis*) from Chili, a Maned Goose (*Bernicla jubata*) from Australia, purchased; an Egyptian Gazelle (*Gazella dorcas*) from Egypt, deposited; a Frazer's Squirrel (*Sciurus fraseri*) from Ecuador, a Black Sternothere (*Sternothærus niger*) from West Africa, received in exchange.

UNDERGROUND TEMPERATURE[1]

OBSERVATIONS on a very elaborate scale have been received from the important mining district of Schemnitz, in Hungary. A request for observations was sent by the Secretary, in 1873, to the Imperial School of Forests and Mines at Schemnitz, and on the receipt of two thermometers a Committee was formed to plan and carry out observations. The leading part in the observations has been taken by Dr. Otto Schwartz, Professor of Physics and Mathematics, who has furnished an elaborate report of the results obtained. This is accompanied by a geological report drawn up by Prof. Gustav von Liszkay and by a geological map with plans and sections of the mines.

The two thermometers sent being deemed insufficient for the numerous observations which were contemplated, twenty-five large thermometers were ordered from a local maker (T. T. Greiner), and the ten best of these, after being minutely compared with one of the two thermometers sent—which was non-registering and had a Kew certificate—were devoted to the observations. Three of them were divided to tenths and the others to fifths of a degree Centigrade, and all had bulbs of thick glass to ensure slowness of action. They were found not to change their indications during the time requisite for an observation.

The observations were for the most part taken by boring a hole in the rock to a depth in the earlier observations of ·422, and in the later ones of ·79 of a metre, then filling the hole with water, and after leaving it in some cases for a few hours, in others for several days, to plunge a thermometer to the bottom of the hole, and after thirty or forty-five minutes take it out and read it. The tenths of a degree were read first, and there was time for this to be done before the reading changed. As a rule three observations were taken in each gallery, two of them in bore-holes to give the temperature of the rock, and the third in the air of the gallery at an intermediate position. Pyrites and also decaying timber were avoided as being known to generate heat, and as far as possible currents of air and the neighbourhood of shafts were avoided also.

A table, which forms part of Dr. Schwartz's report, contains observations made in no fewer than thirty-eight galleries. Besides the temperatures, it gives the depth of the place of observation beneath the shaft-mouth and the height of the latter above sea-level. Dr. Schwartz takes exception to a few of the observations in the table, as being vitiated by the presence of pyrites or by currents of air.

All the galleries mentioned in the table are classified according to the shafts with which they are connected, and there are for the most part six of these galleries to each shaft. In the final reductions, Dr. Schwartz compares the temperature in the deepest gallery of each shaft with the assumed mean annual temperature of the ground at the shaft-mouth. For determining this latter element the following data are employed.

The mean temperature of the air at the School of Mines, from twenty years' observation, is 7°·2 C. at the height of 612·6 metres above sea-level. The shaft-mouths are at heights of from 498 to 763 metres above sea-level, and it is assumed that the temperature of the air falls 1° C. for 100 metres of elevation. It is further assumed that the mean temperature one metre deep in the soil is, in these particular localities, 1° C. higher than the mean temperature of the air. The reasons given for this last assumption may be thus summarised:—

1. Observations in various localities show that in sandy soils the excess in question amounts on the average to about half a degree Centigrade.

2. In this locality the surface is a compact rock which is highly heated by the sun in summer and is protected from radiation by a covering of snow in winter; and the conformation of the hills in the neighbourhood is such as to give protection against the prevailing winds. Hence the excess is probably greater here than in most places, and may fairly be assumed to be double of the above average.

Omitting one shaft (Franz shaft), in which, owing to the presence of pyrites, the temperatures are abnormal, the following are the principal results:—

	Depth metre		Quotient, metre per 1° C.	Feet per
Elizabeth shaft	417	8·5	49·1	89·5
Maximilian ,,	253	6·4	39·5	72·0
Amalia ,,	285	8·1	35·2	64·2
Stefan ,,	218	7·2	30·3	55·2
Siglisberg ,,	414	8·1	51·1	93·2
Sums, &c.	1587	38·3	41·4	75·5

The best mode of combining the results from these five shafts is indicated in the last line of the above table, where the sum of the depths is compared with the sum of the increments of temperature. We have thus a total increase of 38°·3 C. in 1,587 m.; which is at the rate of 1° C. in 41·4 m., or 1° F. in 75·5 feet.

As these results depend on an assumption regarding the surface-temperature, it seems desirable to check them by a comparison of actual observations, namely, by comparing the deepest with the shallowest observation in each mine. We thus obtain the following results:—

	Difference of depth, metres.	Difference of temperature, Cent.	Quotient metres per deg. Cent.	Feet per deg. Fahr.
Elizabeth shaft	145·2	4·6	31·6	57·6
Maximilian ,, ...	191·6	3·9	49·1	89·5
Amalia ,, ...	228·2	5·1	44·8	81·7
Stefan ,, ..	82·0	4·7	17·4	31·7
Siglisberg ,, ...	400·3	8·0	50·0	91·2
Sums, &c.	1047·3	26·3	39·8	72·5

Combining these results in the same manner as the others, we have a total difference of 26°·3 C. in 1047·3 metres, which is at the rate of 1° C. in 39·8 metres, or 1° F. in 72·5 feet.

The near agreement of this result with that obtained from comparison with the assumed surface-temperature is very satisfactory. The mean of the two would be 1° F. in 74 feet.

The rocks consist, for the most part, of trachyte and greenstone.

Dr. Schwartz concludes his report with the suggestion that the heat developed by the decomposition of pyrites and galena in seams which are not altogether air-tight and water-tight, may possibly be utilised as a guide to the whereabouts of metallic lodes; and that "we shall thus obtain, by means of the thermometer, scientific information which the ancients sought by means of the divining-rod."

Thanks are due to M. Antoine Péch, Ministerial Councillor, and Director of the Mines, and to Herr Edouard Poschl, Director of the School, for energetic co-operation in this extensive and valuable series of observations.

Mr. Lebour, having been requested to supplement the above *résumé* of the Schemnitz observations by an account of the connection (if any) between the geological and thermal conditions of the several mines, as indicated by a comparison of the reports of Dr. Schwartz, and Prof. von Liszkay, remarks:—

"The rock at all the mines except Franzschacht is gree hornblende-andesite (*in German* Grünstein-trachyt), a compact fine-grained crystalline, more or less vitreous rock, containing crystals of oligoclase and hornblende, but *no quartz or sanidine*. This rock is a good heat-conductor, with a conductivity probably nearly approaching that of 'Calton trap rock.'

---

[1] Report of the British Association Committee on Underground Temperature, by Prof. Everett.

"The Franzschacht is sunk in rhyolite (a highly siliceous vitreous trachyte), a rock, the conductivity of which would presumably be nearly the same as that of hornblende-andesite, probably a little greater. Elements of temperature-disturbance are, however, present in the form of thermal springs, and, possibly, in the proximity of a basaltic cone. This last element of disturbance is, I should imagine, a very doubtful one indeed, although Councillor A. Péch appears to think it of importance. The rate of increase, as deduced from observations in the rhyolite here, was 1° C. for 40·55m., or about 1° F. for 74 feet.

"The report brings out strongly the important variations of rock-temperature which may be, and are occasionally, generated by the decomposition of metallic sulphides, a point which I think is here prominently mentioned for the first time."

At the request of Mr. Lebour, observations have been taken by Mr. Matthew Heckels, Manager of Boldon Colliery, between Newcastle and Sunderland, in holes bored upwards to a distance of ten feet from some of the deepest seams.

The mine is described as "perfectly dry," and those parts of it in which the observations were made are quite free from currents of air. The surface of the ground is tolerably level, and is ninety-seven feet above Trinity high-water mark.

Hole No. 1 is bored up from the roof of the Bensham seam. The thermometer—one of the new slow-action instruments, not self-registering—was placed at the end of the hole (so as to be ten feet within the rock) and protected by air-tight plugging. The surrounding strata consist of arenaceous shale, known as "grey metal." The distance of the thermometer from the surface of the ground overhead was 1,365 feet.

The hole had been standing idle for some time when the thermometer was inserted, April 5, 1876. The first reading was taken April 26, and was 75°, the surrounding air being at 75½°, and almost stagnant. The readings were repeated during four consecutive weeks, without change of the indications.

Hole No. 2 is in the same vertical with No. 1, and is bored up (also to the height of ten feet) from a deeper seam—the Hutton seam. The same thermometer was employed, and in the same manner. The surrounding strata consist of a close, compact sandstone known as "hard post." The distance of the thermometer from the surface of the ground overhead was 1,514 feet. Immediately after the drilling of the hole, June 6, 1876, the thermometer was inserted, and on July 4 the first reading was taken, namely, 81°. On July 24 it had fallen to 79½°, and on August 1 to 79°. Readings taken on August 15 and 29 and September 1 also showed 79°, the surrounding air having never altered from the fixed temperature, 78½°. It would therefore appear that the first observation in this hole was 2° too high, owing to the remains of the heat generated in boring, notwithstanding the lapse of four weeks which had intervened. Four readings have since been taken at regular intervals, ending with July, 1877, and the same temperature, 79°, continues to be shown.

Assuming 48° as the mean annual temperature of the surface, we have the following data for calculating the rate of increase downwards:—

Surface	48°
1,365 feet	75°
1,514 feet	79°

For the interval of 149 feet between the two holes we have an increase of 4° F., which is at the rate of 1° F. in 37 feet.

For the whole depth of 1,514 feet from the surface to the lower hole we have an increase of 31°, which is at the rate of 1° F. in 49 feet.

In explanation of the length of time required for the heat of boring to disappear in the second hole, Mr. Heckels remarks that "it required two men sixteen hours with a hand-boring machine to drill this hole, so hard is the stratum." He further says: "The tool by which this hole was bored, on being drawn out, was too hot to allow it being touched with the hand, so that the temperature of the hole, on being finished, must have been considerable; and no doubt it would be when we consider the immense pressure required to bore holes in such strata as this." With respect to the permanent temperature, 78½°, of the surrounding air, Mr. Heckels remarks: "The air of this district is almost stagnant, and what circulation there is will have travelled a distance of three miles underground; and hence it may be expected to be itself pretty near the temperature of the rocks through which it is circulating."

The dryness of the mine, the absence of currents of air, and the great depth render these observations extremely valuable for the purpose which the Committee have in view, and their best thanks are due to Mr. Heckels and the proprietors of the colliery for the trouble and expense which have been incurred in procuring them. Observations will shortly be taken in another bore in the same colliery.

During the past year the first observations have been received from India. They were taken by Mr. H. B. Medlicott, M.A., of the Geological Survey, in bores made in search of coal, and have been published by him in the "Records of the Geological Survey of India," vol. x., part 1. The instrument employed was a "protected Negretti" thermometer sent by the secretary of this Committee to Dr. Oldham, the director of the Survey. A Casella-Miller thermometer was used to check the observations, but was found much less sensitive and steady, and its readings, though placed on record, are therefore left out of account by Mr. Medlicott in his reductions.

The observations were taken in three bores, at places named Khappa, Manegaon, and Moran; but the observations at Moran were made only four hours after the boring tool had been at work, and the Khappa bore exhibited a strong bubbling, besides other marks of convection. The results obtained at these two bores must therefore be discarded; but in the Manegaon bore everything was favourable for satisfactory observation. "It was closed on April 24, 1875, so that it had been at rest for twenty months. There is only one guide-pipe ten feet long at the top of the bore, there never having been any pressure of water in the hole. The position is low, and the water had always stood at or near the mouth of the tube. There was no difficulty in removing the plug. The very equable series of temperatures is the natural result of these conditions. The observations were taken in the evening of the 5th and morning of the 6th of December. At 5 P.M. the air-temperature was 72°; at 8 P.M., 59°; at 8 A.M., 65°; at 11 A.M., 84°. The slight decrease of temperature in the top readings is a good proof of the perfectly tranquil conditions of observation. It is no doubt due to the excess of summer heat not yet abstracted; and it is apparent that that influence reaches to a considerable depth—quite to sixty feet." The following are the observations:—

Depth, feet.	Temperature, Fahr.	Depth, feet.	Temperature, Fahr.
10	81·15	150	82·7
20	81·1	200	83·3
40	81·0	250	84·0
60	81·0	300	84·65
80	81·3	310	84·70
100	81·8		

This last observation was in mud, the hole, which had originally a depth of 420 feet, having silted up to such an extent that 310 feet was the lowest depth attainable. The increase from 60 feet downwards is remarkably uniform, and the whole increase from this depth to the lowest reached is 3°·7, which is at the rate of 1° F. for 68 feet.

The elevation of Manegaon is estimated at 1,400 feet. It lies "in an open valley of the Satpuras, traversed by the Dudhi River, south of the wide plains of the Narbada Valley, about half-way between Jabalpur and Hoshungabad, which are 150 miles apart." Jabalpur is 1,351 feet above sea-level, and has a mean annual temperature of 75·2. Hoshungabad is 1,020 feet above sea-level, and has a mean annual temperature of 78·3.

"The geological conditions of the position are favourable for these observations. The rocks consist of steady alternations, in about equal proportions, of fine softish sandstones, and hard silty clays of the upper Gondwana strata, having a steady dip of about 10°. . . Strong trap dykes are frequent in many parts of the stratigraphical basin; but there are none within a considerable distance of these borings. There are no faults near, nor any rock-features having a known disturbing effect upon the heat-distribution."

Mention was made in last report (p. 209) of two methods which had been suggested by members of the Committee for plugging bores to prevent the convection of heat. Mr. Lebour, at the request of the Committee, has conducted experiments during the past year on both forms of plug. He reports that:—

"In accordance with Sir W. Thomson's suggestion, discs of india-rubber fixed to the lowering wire above and below the thermometer have been tried. The chief difficulty met with was the unwieldiness of the armed portion of the wire, which could not be wound and unwound from the drum, owing to the fixed disc-holders. This difficulty prevented the placing of the discs anywhere but at the extremity of the wire, whereas it would be very desirable to have a large number of them at intervals along the greater part of its entire length. Discs for a 2½-inch bore were found to work well with a diameter of 2¼ inches. The lowering, and especially the raising, of the wire armed with the disc-plugging were very slow operations, owing to the resistance opposed by the water to the passage of the discs.

Experiments with the form of plug devised by Mr. Lebour himself were continued with a set of better made plugs. "The great disadvantage of this system of plugging is the necessity for using two wires, one to lower the thermometer and plug as usual, and the other to let down weights upon the upper ends of the plugs, when they are to be expanded, and to remove them when they are to be collapsed. This necessitates not only the ordinary drum for the first wire, but also an independent reel for the second. With care, however, and after some practice, the apparatus was found to work well; but it certainly is extremely inconvenient for rapid work, as it requires a good deal of setting up."

Experiments were made with both forms of plug at the depth of 360 feet, in a bore of the total depth of 420 feet. In the one case, eight india-rubber discs were employed, four above and four below the thermometer; in the other, two collapsible plugs, one above and the other below. The experiments had chiefly in view the mechanical difficulties of the subject, and are not decisive as to the sufficiency of the plugs to prevent convection.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

PROPOSED NEW UNIVERSITY.—A movement has for some time been on foot for the establishment of a new university in the north of England, and on Tuesday last week a deputation, which included the Rev. Dr. Gott (Vicar of Leeds), Mr. Edward Baines, Prof. Thorpe, Prof. Rücker, and Mr. R. Reynolds, waited upon the Mayor of Bradford, Mr. B. Priestly, with the object of inducing the Corporation of Bradford to adopt a memorial to the Privy Council in favour of the proposal. The Mayor intimated that the matter would be referred to the Finance and General Purposes Committee of the Corporation for consideration.

FRANCE.—A commission of twenty-two members has been appointed by the Chamber of Deputies of the French Republic, to prepare a general law on primary instruction.

Two new professorships of botany have been created in the faculties of Lille and Rennes.

PARIS.—The medical course at the University is attended at present by 23 ladies, including 12 Russians, 6 English, and 5 French. Since 1865, 30 ladies have studied medicine at Paris, 9 of whom have received the doctor's diploma.

HIGHER FEMALE EDUCATION.—The subject of the admission of female students to the universities is exciting at present an unusual degree of discussion in Germany as well as in England. In this connection we notice the publication of a letter from Prof. G. H. Meyer, of the medical faculty of Zurich, in which he states, as the result of the experience of a number of years with female students, that he can detect no difference in the average amount of talent and application shown by the representatives of the two sexes under his charge. From a social as well as a professional standpoint, the advanced position taken by the University of Zürich in this direction, during the past few years, is shown to be justified.

KÖNIGSBERG.—The university is attended at present by 655 students, including 42 in the theological faculty, 174 in the legal, 134 in the medical, and 305 in the philosophical. But 42 are from outside of Prussia. The corps of instructors numbers 40. The university possesses a library of 155,000 volumes, an observatory, the zoological museum founded by von Baer, and numerous clinics. On February 2 the eminent philosopher, Herr Rosenkranz, celebrated the fiftieth anniversary of his receiving his doctor-diploma. The German Emperor, the Crown Prince, and all the German Universities, sent congratulatory telegrams and addresses.

HALLE.—On February 27 the 150th anniversary of the establishment of an agricultural chair was celebrated at the Halle University. At the same time the fifteenth anniversary of the opening of the Halle Agricultural Institute, under the direction of its founder, Prof. Kühn, was solemnised. A torchlight procession and banquet were followed by the laying of the foundation-stone for a new geological museum, which is principally destined to contain a geognostical collection of the most important formations in their natural form and succession.

MUNICH.—The rapid increase in the attendance shows that this young University is taking a leading position in Germany. At present the students number 1,360, an increase of over 200 on 1876–77. The philosophical faculty contains 400, and the medical 340. Countries outside of Bavaria are represented by 346. The corps of instructors number 114.

GIESSEN.—The university is attended at present by 315 students, of whom 237 are natives of Hesse. There are but 16 students of chemistry, a striking contrast to the numbers which were wont to flock from all quarters to Liebig's laboratory.

MARBURG.—The number of students in attendance on the university during the past winter was 415. They were divided among the faculties as follows:—Theology 51, law 85, medicine 100, philosophy 179. The Prussian students numbered 263.

BONN.—The professorship of geology and palæontology in this university has been offered to the well-known geologist, Prof. von Seebach, of Göttingen.

KIEL.—The vacant chair of botany is to be filled by Prof. A. Engler, of Munich.

DRESDEN.—A congress of representatives from all the German technical institutions is to take place at Dresden shortly after Easter.

LEIPZIG.—A young lady has taken here, for the first time, the degree of Doctor of Jurisprudence in the legal faculty.

PRUSSIA.—The number of legal students in the various universities has increased so rapidly of late years that they now form three-tenths of the total number.

GERMANY.—From statistical results published by the *Neue Deutsche Schul Zeitung*, it is shown that 60,000 schools with 6,000,000 pupils are in existence in Germany, for a population of about 40,000,000 inhabitants.

MADRID.—The Royal School of Mines has recently celebrated its 100th anniversary and published a handsome historical work in commemoration of the event.

UPSALA.—The University is attended at present by 1,370 students, consisting of 331 in the theological faculty, 145 in the legal, 181 in the medical, and 713 in the philosophical. The corps of instructors numbers 110, including 30 ordinary and 9 extraordinary professors.

SCIENTIFIC SERIALS

Reale Istituto Lombardo di Scienze e Lettere, Rendiconti, vol. xi., fasc. i. and ii.—On some propositions of Clausius on the theory of potentials, by M. Beltrami.—On the composition of cheeses, and on the emanation of fat from their albuminoid substances during maturation, by MM. Musso and Menozzi.—On determination of the nitrogen in milk and its products, by M. Menozzi.—On the resistance of the helices of telegraphic electro-magnets, by M. Ferrini.—Experimental researches on heterogenesis; on the limit of productivity of organic solutions (third communication), by MM. Maggi and Giovanni.—Chemical manures, the agrarian industry, and funded property, by M. Gaetano.—On a reaction of substances reductive in general, and in particular of glucose, by M. Pollacci.—On granite in the serpentine formation of the Apennines, by M. Torquato.

Morphologisches Jahrbuch, vol. iv. part 1, commences with a paper of 111 pages by Max Fürbringer on the comparative anatomy and development of the excretory organs of vertebrata. Nearly fifty figures are given to illustrate the early stages of these organs in the common frog and salamander, a full *résumé* is given of all observations on those of other vertebrates; together with a discussion on their homologies, and on their indications of relationship to the segmental organs of worms.—A careful description of the anatomy of *Isis neapolitana*, n.sp., is given by

G. von Koch.—Dr. H. von Ihering's contribution to the anatomy of Chiton deals chiefly with the sexual apparatus, the kidney, and the muscles. He show that in Chitonidæ the sexes are undoubtedly separate, and that the ova are fertilised in the ovary.—Observations on the formation, fertilisation, and segmentation of the animal egg, by Oscar Hertwig, part 3, 20 pages, 3 plates. This part deals with the ova of the star-fish, Asteracanthion.

Zeitschrift fur wissenschaftliche Zoologie, vol. xxx. part 2.—Contribution to the knowledge of the flagellate infusorians and some related organisms, by O. Bütschli, 78 pp. 5 plates, describing or criticising a great number of species.—On the lungs of *Birgus latro* (land crab), by C. Semper.—The copulatory organs of plagiostomes, by K. R. Petri, 48 pp. 3 plates.—The central nervous system of the alligator, by Rabl-Rückard, 38 pp. 2 plates.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 28.—"Measurements of Electrical Constants. No. II. On the Specific Inductive Capacities of Certain Dielectrics," by J. E. H. Gordon, B.A. Camb. First Series. Communicated by Prof. J. Clerk Maxwell, F.R.S. (Abstract.)

The author has, under Prof. Clerk Maxwell's directions, carried out some measurements of specific inductive capacities by a new method.

The author finds that all his results are much lower than those obtained by previous experimenters, and suggests that the fact may perhaps be explained on a supposition that the specific inductive capacity of dielectrics increases from an inferior to a superior limit during the first small fraction of a second after the commencement of the electrification. He discusses this question at some length in his paper.

"On the Thermo-Electric Properties of Liquids," by G. Gore, LL.D., F.R.S.

In this communication the author has described an improved apparatus for examining the thermo-electric properties of liquids, by the use of which, with the precautions stated, all sources of error in such experiments appear to be removed; he has also described a number of experiments he has made with it, and the results obtained.

By employing a sufficient number and variety of electrically-conducting solutions, of acids, salts, and alkalies, in those experiments, he has discovered several exceptions to the usual effect he had formerly obtained, viz., that acid liquids are thermo-electro-positive, and alkaline ones thermo electro-negative, and has sketched a diagram representing the thermo-electric behaviour of heated platinum in three of the exceptional liquids.

Reasoning upon the satisfactory results obtained, he concludes:—(1) That the electric currents are not produced by chemical action; (2) Nor by a temporary disassociation of the constituents of the liquid; (3) Nor by the action of gases occluded in the metals; (4) But that they are produced purely and solely by the heat, and that heat disappears in producing them; (5) That they are immediate or direct effects of the heat, and that aqueous conducting liquids, therefore, possess true thermo-electric properties; (6) That the current is a result of a difference of thermic action at the surfaces of the two pieces of metal; (7) That it is a product of a suitable molecular structure of the liquid, a change of such structure resulting from alteration of temperature, and a direct conversion of heat into electricity; and (8) That the circumstance which is most influential in enabling heat to produce the currents, and most determines their direction and amount, is a suitable molecular structure of the *liquid.*

By means of the apparatus and process described, he has discovered irregular molecular changes in several of the liquids examined; and as molecular changes are the bases of various physical and chemical alterations, he suggests the use of this apparatus and method as a new one for discovering anomalous molecular alterations, and other coincident physical and chemical cces, in electrically conducting liquids; and for detecting differences of electric potential between metals and liquids at different temperatures.

By reasoning upon the different results obtained, he concludes also as probable, that when a piece of metal is simply immersed in a suitable liquid, a change of temperature occurs; and this (if correct[1]) is a parallel fact to that of the production of electricity by simple contact only. The results also support the contact theory of voltaic electricity.

The paper concludes with several suggestions of new lines of research suggested by the experiments, one of which is the construction of a new thermo-electro-motor.

Chemical Society, March 30.—Anniversary meeting.—Dr. Gladstone, president, in the chair.—The following is a brief summary of the president's address:—The bye-laws have been thoroughly revised. Successful efforts have been made to expedite the publication of the *Journal*, and a sub-editor, Mr. C. E. Groves, has been appointed. The Research Fund now amounts to 4,000*l.*, and already two papers have resulted from the assistance rendered by it to investigators. The President hopes that many chemists, especially those to whom the pursuit of chemistry has become a source of wealth, will contribute to this important fund. During the past year an independent body, the Institute of Chemistry of Great Britain and Ireland has been formed and incorporated; its objects, which are quite distinct from those of the Chemical Society, are the encouragement of the study of chemistry and the maintenance of the profession on a sound and satisfactory basis. Sixty-five papers have been read during the past session, and two lectures have been delivered. There are at present 965 Fellows. The Society has lost by death one eminent foreign member, M. Regnault, and, besides, Messrs. R. Apjohn, J. J. Griffin, W. Gossage, T. Hall, E. L. Koch, M. Murphy, Dr. Noad, and E. F. Teschemacher. After several votes of thanks, &c., the following officers were elected for the ensuing year:—President—J. H. Gladstone, Ph.D., F.R.S. Vice-presidents—F. A. Abel, C.B., Sir B. C. Brodie, W. De la Rue, E. Frankland, A. W. Hofmann, W. Odling, Lyon Playfair, A. W. Williamson, T. Andrews, W. Crookes, F. Field, N. S. Maskelyne, H. E. Roscoe, R. Angus Smith. Secretaries—W. H. Perkin and H. E. Armstrong. Foreign Secretary—Hugo Müller. Treasurer—W. J. Russell. Council—Lothian Bell, M. Carteighe, A. H. Church, W. N. Hartley, C. W. Heaton, D. Howard, G. Matthey, E. Riley, W. A. Tilden, R. V. Tuson, R. Warington, C. R. A. Wright. During the meeting it was announced that Mr. Warren De la Rue had presented the Research Fund with the sum of 100*l.* on the condition that it should be devoted to any one important research.

Anthropological Institute, March 12.—Mr. John Evans, D.C.L., F.R.S., president, in the chair.—Prof. A. Graham Bell read a paper on the natural language of the deaf and dumb. The author stated that in most cases dumbness was merely a consequence of deafness, and does not arise from any deficiency in the vocal organs, but merely from the inability to acquire articulate language, from want of means of imitating it. This can be supplied by teaching. The dogma, "without speech, no reason," is not well founded. Deaf-mute children think in pictures. Thence they form a language of signs which, as contractions of it become understood, develops into a conventional language, but its extent is very limited. No deaf-mute has been found who had formed the idea of a Supreme Being. About the commencement of the present century the Abbé de l'Epée opened an institution for the education of deaf-mutes. The tendency of education was to render the language more and more conventional by means of contractions. Of this Mr. Bell gave many interesting examples. The result of systematic education has been to enable the deaf-mutes to form a community among themselves, using a real language, representing abstract ideas as well as mere objects. Not only so, but the language has idioms of its own; for example, the objective case comes first—thus, "the boots made the bootmaker." This is a difficulty, and perhaps a mistake in the education; it affords, however, a useful subject for anthropological inquiry into the analogy with the development of spoken language. In illustration, Mr. Bell delivered the Lord's Prayer in the sign language. The North American Indians have a sign language, the same in character, but less developed, than that of the deaf-mutes. The language of the deaf-mutes is beginning to split into dialects.

Photographic Society, March 12.—J. Glaisher, F.R.S., president, in the chair.—Papers were read by Dr. van Monckhoven on the fading of carbon prints, and the suppression of bichromates in carbon printing, and by Edwin Cocking, on non-converging perpendiculars in architectural photographs. Dr. Monckhoven, in his paper, asserts that neither hot water nor alum fix carbon prints, and although excess of bichromate of potash is removed, still the chromic salt, which has rendered the gelatine insoluble, not only remains, but undergoes a change by subsequent exposure to light, and thus accelerates the action of light upon the organic colour of the pigment, which fades rapidly. He suggests a new fixing agent, bisulphite of soda, and for colour some of the oxides of iron, mixed when moist, with glycerine and gelatine, which he states are absolutely unalterable by exposure to light.

---

[1] Since writing the paper he has proved, by experiment, that when a sheet of platinum is immersed in various saline, alkaline, and acid liquids, a slight rise of temperature takes place; the solutions already employed, in which such a result occurs, are enumerated.

EDINBURGH

Royal Society, March 8.—Sir William Thomson in the chair.—Prof. Tait read a paper on thermal conductivity, the result of experiments during the last ten years. His results for iron are much the same as those obtained by Principal Forbes. He had solved the following problems:—1. That, with the exception of iron, in no case as yet tried does a pure metal diminish in thermal conductivity as the temperature rises. 2. That different specimens of the same metal, as, for instance, two kinds of copper differ much the same relatively in thermal and in electric conductivity. 3. A substance which is pretty constant as a conductor of electricity is also pretty constant in thermal conductivity. Among the difficulties encountered was the alteration of the zero point of the thermometers used—Kew standards—after being heated to a high temperature. This affects only the absolute values slightly, but not the general character of the results. Another difficulty was the oxidation, during heating, of the short bars employed to measure the heat lost by radiation and convection at different temperatures. This was almost completely overcome.—Prof. Fleeming Jenkin and Mr. J. A. Ewing communicated a paper on the wave forms of articulate sounds obtained by the aid of the phonograph. Their results show that Helmholtz's theory of vowel sounds, viz., that for the production of any one vowel certain fixed notes are necessary, is not tenable, as they obtained vowel sounds under circumstances which rendered the presence of some of these notes impossible. They have also made out that every vowel and every consonant is reversible. This is true also of such single sounds as *ng*, *th*, *ch*, &c. A number of curves were exhibited showing the form of the indentations on tinfoil produced by various articulate sounds, multiplied about 400 times by means of a system of levers.—A paper by Mr. George M'Gowan on the action of the chlorides of iodine on acetylene and ethylene, was read by Mr. J. Y. Buchanan.

PARIS

Academy of Sciences, April 1.—M. Fizeau in the chair.—The following papers were read:—On some applications of elliptic functions (continued), by M. Hermite.—Parameters of elasticity of solids, and their experimental determination, by M. de Saint-Venant.—On the specific heats and the heat of fusion of gallium, by M. Berthelot. The liquid specific heat was found to be 0·0802; the solid, 0·079. Referred to 69·9 as the atomic weight, the heat of fusion was 1·33 cal. As with mercury, lead, tin, and bismuth, the solid and liquid specific heats, taken at the same temperature, are closely alike. The specific atomic heat of gallium (liquid 5·59, solid 5·52) is about the same as that of aluminium (5·53) and that of glucinium (5·64).—Action of oxygen on acid chlorides, bromides, and iodides; compounds of aluminium, by M. Berthelot.—On the movements of storms, by M. Faye.—On the whirlpools of watercourses, by M. Belgrand. He notices some phenomena of streams as illustrating M. Faye's theory.—Observations on the nature of the plants collected in the group of *Nœggerathia*; types of *N. flabellata*, Lindl. and Hutt., and *N. cyclopteroides*, Gœpp., by M. de Saporta.—The conidia of *Polyporus sulfureus*, Bull, and their development, by M. de Seynes.—Action of the sun on the magnetic and electric fluids of the earth, by M. Quet. The subject is treated mathematically.—On the linear differential equation which connects with the modulus the complete function of the first species, by M. Tannery.—On the kinematics of continuous figures on curved surfaces, and, in general, in plane or curved varieties, by M. Levy.—Actinometric measurements made in Algeria during the summer of 1877, by M. Violle. These were partly made in the dry Saharan climate of Laghouat, 466 kilom. south of Algiers, partly at Fagrait, a height of 993 m., and at Khanza, 740 m. ower. The method was the same as M. Violle used on the top of Mont Blanc two years ago. The numbers obtained for the so constant in the former case, by Pouillet's and Forbes' formulæ, w 2·40 and 2·42; both less than 2·54, the value got on the top Mont Blanc. The ratio of the intensities of solar radiation the plain and on the mountain was 0·915.—On astronomi refraction, by M. Makarevitsch.—On the physical propert and the specific heat of glucinium, by MM. Nilson and Petterssc They obtained large quantities of crystalline glucinium by he ing to a red heat a cylindrical mass of iron, containing, in a h closed with a screw, some of the chloride and some sodium fre from its oil of naphtha. The compound of marine salt a glucinium found after cooling, is washed with water, and t reduced metal (impure) appears in bright spangles, or dendrit or small globules. The density of pure glucinium is calculat to be 1·64; specific heat 0·4084. The atomic weight Be = 13 and the formula for the oxide Be_2O_3 (assigned by Berzelius) a confirmed.—On a reaction peculiar to some polyatomic alcoho by M. Klein. It is shown that all the ethers of mannite a its derivatives possess rotatory power.—On a new method separation of arsenic from other metals, by MM. De Clermo and Frommel. This is based on the fact that while a lar number of hydrates of sulphides are dissociated at 100° in sulphuretted hydrogen and oxide, sulphide of arsenic is t only one which gives a soluble oxide, arsenious acid. Hence, a mixture of sulphide of arsenic and other sulphides be broug to boiling, the sulphides will all be oxidised, and remain i soluble in the water, except arsenious acid, which may then easily isolated.—On melilotol, by Mr. Phipson. This is a ne oily product got by distilling with water, dried *Melilotus offi nalis*, then treating the distilled water with ether which dissolv the substance, so that it is got very pure after evaporation. it is due the odour of melilot and hay.—Telephone employ as galvanoscope, by M. D'Arsonval. The worst construct instrument is found to be at least 100 times more sensitive th the nerve for revealing weak electric tensions. It is very w adapted for studying the electric tetanus of muscle.—On anthr in the horse and the dog; phlogogenic action of anthrac blood, by M. Toussaint. The phlogogenic matter accompan ing the bacterides is more or less active according to the sour whence these latter come.—On the epoch of formation of t cloaca in the embryo of the common fowl, by M. Cadiat.

GOTTINGEN

Royal Society of Sciences, January 5.—On a class differential equations which are integrable by Abel's or ellipt functions, by M. Fuchs.—On the affinities and systematic signi cance of *Ceroxylon andicola*, by M. Drude.—Some words on t origin of language, by M. Benfey.

THURSDAY, APRIL 18, 1878

THE COMING TOTAL SOLAR ECLIPSE

THERE is no doubt whatever that the eclipse which will sweep over the United States next July will be observed as no eclipse has ever been observed before. The wealth of men, the wealth of instruments, and the wealth of skill in all matters astronomical, already accumulated there, makes us Old Country people almost gasp when we try to picture to ourselves what the golden age will be like there, when already they are so far ahead of us in so many particulars.

Draper, Hall, Harkness, Holden, Langley, Newcomb, Peters, Peirce, Pickering, Rutherfurd, Trouvelot, and last, but not least, Young, are the names that at once ran easily off the pen to form a skeleton list, capable of considerable expansion with a little thought, when one thinks of the men who will be there. One knows too that all the enthusiasm of devoted students and all the appliances of modern science—appliances in the creation of which many of those named have borne so noble a part—will not be lacking. So that we may be sure that not only all old methods but all possible new ones will be tried to make this year one destined to be memorable in the annals of science side by side with 1706, 1851, 1860, and other later years.

Thank Heaven, too, there is no necessity that the thankless task of organising an "Eclipse Expedition" from this country should fall on any unfortunate individual, among other reasons because—and this is a very hopeful sign of increasing general interest taken in scientific work—Messrs. Ismay, Imray and Co., the owners of the White Star Line, have expressed in the warmest manner their desire to aid English observers by a considerable reduction of fares, and the directors of the Pennsylvanian Railway Company, as the readers of NATURE have already been made aware, have done the like in the case of observers coming from Europe in their individual capacity.[1]

The progress in that branch of knowledge which requires the aid of eclipse observations has been so rapid during the last few years that the eclipse of 1868, though it happened only ten years ago, seems to be as far removed from the present as the Middle Ages are in regard to many other branches of culture. The work done by the spectroscope since that year, when in the hands of Janssen, Pogson, Herschel, and others, it added so enormously to our knowledge, has gradually covered larger and larger ground, and each successive eclipse in 1869, 1870, 1871 and 1875, has seen some variations in its use, so that its employment has proved the most novel, if not the most powerful, side of the attack.

Young's work of 1869 will no doubt form the key-note of much that will be done this year so far as the coronal atmosphere is concerned. It will be remembered that Young in 1869 observed a continuous spectrum, while Janssen in 1871 observed a non-continuous one, for he recorded the presence of the more prominent Fraunhofer lines, notably D. This positive observation from so distinguished an observer demands attention, not only on its own account, but because of the question which hangs upon it, which is this: Does the corona reflect solar light to us or does it not, and if it does, *where* are those particles which thus act as reflectors? On this point the photographs taken in Siam in 1875 are silent, as the method employed was not intended to discriminate between a continuous and a discontinuous spectrum.

But although this point remains, how greatly has the ground been cleared since 1860. That wonderful line, "1474," is more familiar to us now! and yet there has been almost a chapter of accidents about it. In the first place, with regard to this line above all others, there appears to be a mistake in Angström's map; the solar line at 1474 is not due to iron at all; with the most powerful arc there is no iron line to be seen there. Then Secchi attributed it to hydrogen, though I am not aware on what evidence. But whatever be its origin, the fact remains that we now know by its means that the solar hydrogen is traversed and enwrapped by the substance which gives rise to the line to an enormous height, so that it forms the highest portion of the atmosphere which is hot enough to render its presence manifest to us by spectral lines. Here, so far as I know, only one point of difference remains. In 1871 I most distinctly saw the line trumpet shaped, that is, with the base broadening as the spectrum of the photosphere was reached, while Janssen saw it stopping short of the spectrum of the photosphere. The importance of this point is that supposing one of us to be mistaken and one or other observation to represent a *constant* condition, then, if the line broadens downwards till the sun is reached we are dealing with a gas lighter than hydrogen, capable of existing at a high temperature, which thins out as the other gases and vapours do in consequence of its vapour density being below that of hydrogen; or, on the other hand, if the line stops short as a constant condition, it represents a substance which is probably dissociated at the lower levels, and is therefore probably a compound gas; and then the question arises whether it has not hydrogen as one of its constituents.

Perhaps I may conveniently refer to a paper of mine which was read at the Royal Society last Thursday in this connection, because it may be that the solar regions most worthy of the closest study at the present time are precisely these higher reaches of the sun's atmosphere. There is little doubt, I think, that around the sun's visible atmosphere matter exists at a temperature low enough not to give us its autobiography in the bright line manner, and there is evidence that matter existing under such conditions, absorbing as it must do some of the sun's light, will, if it remains elemental, give us an absorption of the fluted kind, or again will absorb only in the blue or ultra-violet region.

Now the more the chemistry of the reversing lower layer of the sun's atmosphere—that in which the upper level of the photosphere is bathed—is examined the more metallic is it found to be. For instance, my own work has enabled me to trace with more or less certainty eighteen metallic elements,[1] in addition to those recorded

---

[1] In fact Messrs. Ismay, Imray and Co. have just announced that they will take properly certified observers and bring them home again for the sum of 20*l.*, which is rather less than 1st class single fare; so that English observers will be carried to Denver or the Rocky Mountains and back again for the sum of 34*l.*

[1] These are strontium, lead, cadmium, potassium, cerium, uranium, vanadium, palladium, molybdenum, indium, lithium, rubidium, cæsium, bismuth, tin, lanthanum, glucinum, and yttrium or erbium.

VOL. XVII.—No. 442

by previous observers; but of metalloids in this region I have traced none. The persistency with which metal after metal revealed itself to the exclusion of the metalloids led me to throw out the idea some time ago, that perhaps the metalloids lay as a whole above the metals, and shortly afterwards I obtained evidence which seemed to me of a very satisfactory nature as to the existence of carbon, its presence in the sun's atmosphere being rendered probable by fluted bands, and not by lines. There were two points, however, which remained to be settled before the matter could be considered to be placed beyond all doubt.

The first was to establish that the fluted bands generally present in the spectrum of the electric arc, as photographed, which bands vary very considerably in strength according to the volatility of the metal under experiment, were really bands of carbon—a point denied by Angström and Thalèn.

This point I have settled by two photographs, in which the carbon bands remain the same, though one spectrum is that of carbon in air, the other of carbon in dry chlorine.

The next point was to insure accuracy by the most positive evidence that there was absolutely no shift in the carbon bands. Such a shift is produced when the part of the arc photographed is not perfectly in the prolongation of the axis of the collimator of the spectroscope. Its effect is to throw the lines of iron, for instance, a little to the right or a little to the left of the Fraunhofer lines with which they really correspond.

I have now obtained a photograph which supplies such evidence. There are metallic lines close to the carbon bands which are prolongations of Fraunhofer's lines, while the lines which I have already mapped at W. L., 39·27 and 39·295, in the spectrum of iron, are also absolute prolongations. Therefore there is no shift in the carbon flutings, and the individual members of the fluted spectra in the brightest portion are absolute prolongations of a fine series of Fraunhofer lines in the ultra-violet.

Now how does this connect itself with observations of the upper parts of the solar atmosphere?

Angström has already shown that the true carbon *lines* which we get when a coil and jar are employed are not reversed in the spectrum of the sun, and I have already shown that the calcium spectrum in the sun is similar to the spectrum obtained when the spark, and not the arc, is employed. Accompanying the change from a high to a higher temperature, there is a change in the intensity of the lines—some thicken, others become thinner. We can only match the relative thickness of the solar calcium lines by employing a very powerful coil and jar—so powerful, indeed, that the lines, and not the flutings, of carbon would be visible in the spark given by it. It is fair then to say that if carbon were present with the calcium *in the sun's reversing layer*, we should get the lines of carbon when we get the calcium lines appearing as they do.

As we do not get this evidence, we are driven to the conclusion that the carbon vapour exists not only in a more complicated molecular condition (as is evinced by the flutings) than the metallic vapours in the sun's atmosphere, but at a lower temperature. It must, therefore, exist *above the chromosphere*, that is, in a region of lower temperature. Lower pressure, again, is indicated by the feeble reversal, so that everything points to a high level.

The question is, will this region be recognised during the coming eclipse?

Coming down lower we reach a level better known, and of which, perhaps, the interest during the eclipse will now be less, if we except the possibilities opened out to us by photography. One good photograph of the lines visible in the lower chromosphere will be of incalculable value. Attempts may be made on the cusps just before and after totality, and if only one of these succeeds we shall have the ordinary solar spectrum as a scale. If good pictures near H can be secured, enough information now exists for that region to enable us to determine the chemical origin of the bright lines photographed. These remarks apply to attempts made with spectroscopes furnished with slits in the ordinary way; there is little doubt, however, that the method utilised for the Siam eclipse in 1875, the method suggested by Prof. Young and myself for the Indian Eclipse of 1871, will also be taken advantage of; here the chromosphere itself becomes the slit. A dispersed series of spectral images of the thing itself, instead of the spectrum of a part of the image of it focussed on a slit is obtained, the position of each image in the spectrum enabling its chemical origin to be ascertained if only a comparison spectrum can be secured at the same time.

In 1875, in the expedition to Siam, the photographs of this nature were obtained by means of a prism, and the results obtained by that expedition led me to think that, possibly, this method of using the coronal atmosphere as a circular slit might be applied under very favourable conditions if the prism, or train of prisms, hitherto employed, were replaced by a reflection grating, with which the generosity of Mr. Rutherford has made many of us familiar, for the simple reason that while a prism only gives us one spectrum, a brilliant grating placed at right angles to an incident beam gives us spectra of different orders, so-called, on each side of the line, perpendicular to its surface. Of these two or three are bright enough to be utilised on each side, so that we can get six in all.

To test this notion I made the following experiment with a grating given to me by Mr. Rutherfurd. This magnificent instrument contains 17,280 lines to the inch, ruled on glass and silvered; its brilliancy is remarkable.

In front of the condenser of an electric lamp adjusted to throw a parallel beam, I placed a circular aperture, cut in cardboard, forming a ring some 2 inches in interior diameter, the breadth of the ring being about ⅛ inch. This was intended to represent the chromosphere, and formed my artificial eclipse.

At some distance from the lamp I mounted a 3¾ inch Cooke telescope. Some distance short of the focus I placed the grating; the spectrum of the circular slit, illuminated by sodium vapour and carbon vapour was photographed for the first, second, and third orders on one side. The third order spectrum, showing the exquisite rings due to the carbon vapour flutings, was produced i[illegible]rty-two seconds. The first order spectrum, obtained in the same period of time, was very much over-exposed. It is, therefore, I think, not expecting too much that we should be able to take a photograph of the eclipse, in the third order, in two minutes. Similarly, we may hope for a photograph of the second order in two minutes, and it is, I think, highly probable also that a photograph of the first order may be obtained in one minute. To make assurance doubly sure, the whole of the totality may be used during the coming eclipse, but if there be several such attempts made it will certainly be worth while to try what a shorter exposure will do.

Now, by mounting photographic plates on both sides of the axis, one solidly mounted equatorial of short focal length may enable us to obtain several such photographs, with varying lengths of exposure. I insist upon the solidity of the mounting because, if any one plate is to be exposed during the whole of totality, the instrument must not be violently disturbed or shaken while the eclipse is going on. I think, however, it is quite possible to obtain more than one photograph of the lower order spectra without any such disturbance in this way. The same plate may be made to record three, or even four, exposures in the case of the first order in an eclipse of four minutes' duration, by merely raising or lowering it after a given time, by means of a rapid screw or other equivalent contrivance, so that a fresh portion of the same plate may be exposed. Similarly, the plates on which the spectra of the second order are to be recorded may be made to perform double duty.

If one equatorial thus mounted were to be devoted to each quadrant of the coronal atmosphere, it is certain, I think, that most important results would be obtained.

GIGANTIC LAND-TORTOISES

Gigantic Land-Tortoises, Living and Extinct, in the Collection of the British Museum. By A. C. L. G. Gunther, M.A., M.D., F.R.S. Keeper of the Department of Zoology. (London: Printed by Order of the Trustees, 1877.)

THE recent and extinct gigantic land-tortoises in the collection of the British Museum has just received at the hands of Mr. A. C. L. G. Gunther, Keeper of the Department of Zoology, an elaborate and exhaustive memoir and history. As early as 1872 Dr. Gunther had made much progress in the elucidation of their structure, but in 1874 the osteology of the Mascarene tortoises had still more engaged his attention. Again in 1877 new matter arising from fresh materials imported into England from the Aldabra group of islands, Mauritius, Rodriguez, and the Albemarle and Abingdon Islands, enabled Günther to complete his memoir upon these gigantic land-tortoises, recent and fossil.

This important volume contains a description of the races of the Aldabra group, the extinct races of the Mascarene group (Mauritius and Rodriguez), and lastly, the Galapagos Islands races. Dr. Günther, at p. 10, gives a synopsis of the fossil and living gigantic land-tortoises. He bases his classification upon the presence or absence of the nuchal plate—frontal portion of the skull—condition of the pelvis as to nature of the symphysial bridge, and whether the gular plate is single or double. The Aldabra tortoises, or those of the Aldabra Islands, fall under the first group, or those with the nuchal plate present, gular plate double, and frontal portion of skull convex and with the pelvis having a narrow symphysial bridge. Four species of Testudo, all living, occur in the Aldabra group.

The second group, embracing the Mascarene and Galapagos tortoises, possess no nuchal plate; the symphysial bridge is broad, and the frontal portion of the skull is flat. The Mascarene species, four in number, are all extinct, and are found by Gunther to have a single gular plate and short sternum, whereas the Galapagos tortoises have a double gular plate and rather large sternum, and all but one species (*Testudo ephippium*), from Indefatigable Island, are living.

These deductions arrived at by Dr. Günther after years of long and patient labour, greatly add to our knowledge of the structure of the Testudinæ greatly removed in space; he not only shows that the Aldabra species have definite and almost individualised structure, but that they are entirely different species from their nearest or Mascarene neighbours, a great fact in the distribution of life, over an area once continuous land, but now known to be one of depression, and yet geographically contiguous, the Island of Madagascar only separating them. Here, however, we have not a wide distribution in space, and yet no species seems common to the Mascarene and Aldabra Testudinæ—the living races of the Aldabra group being entirely different from the extinct races of the Mascarenes. Dr. Gunther endeavours to show that in the absence of direct genetic relationship between the tortoises of the Galapagos Islands and the Mascarenes, that some "terrestrial tortoises" were transported through some agency ("stream or current") from the American continent to the Galapagos - and similarly that those of Madagascar or Africa migrated in a similar manner to the Mascarenes. The origin and geographical distribution of species especially terrestrial is always of the highest interest to earnest students of life in its various phases. The history and origin of species, and their distribution, is perhaps one of the most difficult problems now engaging the minds of naturalists, and Gunther refers to the reappearance of the "Indian, Mascarene, and Aldabra gigantic land-tortoises in the Galapagos," as one of these—not, he says, in "typical singularity, but with all the principal secondary modifications reproduced." The greater extension of this large Chelonian type at a former geological epoch seems manifest, when we find remains at Malta corresponding with those of the Galapagos tortoises, and the close affinity between the Galapagos and the Aldabra and Mascarene species, although separated by so vast a distance; we must grant a continuity of land over the region now covered by the Pacific, and which for ages has undergone, and is still undergoing depression. No one can doubt or fail to see the great changes that have taken place in the physical geography of South Africa, whose attenuation towards the south and eastern coasts is due to depression, thus causing the isolation of Madagascar, the Mascarene Islands, and the Seychelles, such severance and island making, through causes long-continued and not equally the same areally in equal times, has produced that specialised or peculiar fauna for which many of these islands are noted, yet partaking largely of the Madagascar or parent types.

These gigantic land-tortoises which appear to have formerly occupied or inhabited the Mascarene Islands, are now only found at Aldabra, one of the Seychelles 1,000 miles further north. This isolation of Madagascar with its surrounding northern and eastern scattered islands and coral reefs alone indicate one continuous and extensive equatorial land. According to Wallace the Mascarene Islands were probably "earliest separated from Madagascar and before any carnivora had reached the country, hence the secure abode of groups of birds incapable of flight"; also to the same causes may be attributed in these islands the development of these gigantic land-tortoises, security, food, and time being three at least important factors for continuity of life; and surpassing as they did all others in size now living on the globe.

Dr. Günther formulates the races of tortoises indigenous to the Galapagos by the want of the nuchal plate, by the long neck and legs, and black shell, flatness of the crown of the skull, and thinness of the osseous carapace.

This diagnosis of the Galapagos races of tortoises shows them to be differentiated from the Aldabra races by the same structural characters as the Mascarene races to which, however, they are closely allied—but differing in not possessing the double gular plate.

Dr. Günther in his elaborate notice of the extinct races of the Mascarene turtles, speaks of their being "sharply and structurally differentiated from the tortoises of the Aldabra group;" he has now ascertained through the possession of complete carapaces from Mauritius and Rodriguez, that there is an "absence of the suture which divides in most land tortoises the gular plate of the sternum into two longitudinal halves." Again, he has proved that the Mascarene tortoises possess no nuchal plate. The solution of these structural differences of the races is due to recent researches and exploration in the Mauritius and Rodriguez, and they have resulted under Gunther's determination in the three following deductions:—

1. That the specimens with a nuchal plate (and with double gulars) come from Aldabra.

2. That the specimens with simple gular (and without nuchal) come from the Mascarenes.

3. That the specimens without nuchal, and with double gular, are Galapagos tortoises.

Dr. Günther's researches conclusively show that the living gigantic tortoises of the Galapagos are more nearly allied or related to the extinct tortoises of the Mauritius, than those living in Aldabra. This generalisation of Dr. Günther's tends to show that there must have been several distinct groups and centres of Testudo ranging widely over the globe, and that some of each still survive in localities widely removed from each other; such being the Mascarene, Seychelles, and Galapagos, with remains found at Malta.

Elaborate osteological details accompany the descriptions of the species in the races of the Aldabra tortoises, the extinct races of the Mascarenes, and the Galapagos species. No less than fifty plates illustrate and accompany the letter-press to this learned memoir or monograph upon the gigantic land-tortoises (living and extinct) now in the collection of the British Museum. R. E.

OUR BOOK SHELF

Treatise on Modern Horology in Theory and Practice. By M. Claudius Saunier, Ex-Director of the School of Horology at Maçon, Chevalier of the Legion of Honour, Honorary Secretary to the Paris Society of Horologers, &c. Translated by Julien Tripplin, Besançon, Watch Manufacturer, and Edward Rigg, M.A., Assayer in the Royal Mint. (London: J. Tripplin.)

M. CLAUDIUS SAUNIER'S treatise, though mainly intended for technical readers, contains a vast quantity of useful and instructive information, likely to be quite as interesting to amateur as to professional horologists. The work, moreover, is largely illustrated by beautiful coloured copperplate engravings, which, as models of accuracy and elegance, cannot be too highly praised. If in anything the book is perhaps scarcely up to the mark, as regards recent improvements in English clockwork; but no doubt such will be fully discussed in the appendix we understand M. Saunier has in hand, and which we hope will be published before the conclusion of the English series. So far as can be judged from the first number, the work of translation is being performed efficiently.

China. A History of the Laws, Manners, and Customs of the People. By John Henry Gray, M.A., LL.D., Archdeacon of Hongkong. Edited by W. G. Gregor. 2 vols. 140 Illustrations. (London: Macmillan and Co., 1878.)

MANY books have been written on China and its puzzling people, and many attempts made to describe and account for the mode of life, the manners, and customs—to Europeans seemingly half childish—of the latter. Hitherto, however, it is safe to say, the Chinese have not been understood. Their jealousy of foreigners, their unwillingness to admit the outside barbarian into the sanctity of their inner life is proverbial, so that the vaguest and most erroneous notions prevail concerning this remarkable people, combined with a sort of tacit conviction that their life in its various aspects is too trivial to be worth inquiring into. A perusal of Dr. Gray's work, we are sure, will greatly tend to dispel these mistaken notions. Dr. Gray evidently possesses an unusual power of winning his way into the friendship of all classes of Chinese, and this, combined with a liberal and tolerant mind and a faculty of careful observation, has enabled him to learn more about the everyday life and thoughts and motives of the people than almost any European has done before him. The work is certainly one of the most instructive that has ever been written on China, and every page is interesting. Family life in all its varied relationships is illustrated by pen and pencil, as is also official life, commercial life, professional or literary life, life in hotels, and life in the street, pawnshops, pagodas, agriculture, fortune-telling, religion, amusements; in short, it would be difficult to point out in what respect the book is defective. The illustrations are very interesting, and have mostly, we believe, been drawn by native artists. The work ought, we should think, to become a permanent standard work on China.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

The Arrangement of Museums

THE subject brought forward by Lord Wharncliffe a few days ago in the House of Lords forms part of a much larger question which sooner or later must occupy the attention it deserves, viz., the best means of collecting and arranging museums for the purposes of instruction.

How few of those who visit the British Museum or South Kensington, amongst the less instructed portion of the public at least, carry away any distinct reminiscence of what they have seen. The mind is bewildered by the immense number of objects presented to it and the absence of any sequence in the arrangement by which to assist the memory. The principles which are recognised as applicable to education in general apply equally to the arrangement of museums in so far as their educational functions are concerned, and consist, not in overwhelming the student with an immense accumulation of facts, but in presenting to his mind only such facts as are important or typical, and in the order in which it is intended they should be remembered. The order in which the knowledge of things is best received and retained by the memory is precisely that in which the things themselves were evolved; consequently, the arrangement which in a museum is best adapted to impart instruction is at the same time that which best records the history of the things exhibited. This consideration appears to determine conclusively the arrangement which ought to be adopted wherever the education of the public is the object to be attained, but museums, whether local or national, have other objects besides the instruction of the public. They are intended for the preservation of antiquities and natural history objects, many of which are not yet classified and have no place assigned to them, and which consequently cannot be arranged in any historic sequence such as I have alluded to. They should afford materials, not for the use of the public only, but for *savants*, in promoting original research, which is one of their most important functions, and which ought not to be sacrificed for the benefit of the common herd of visitors, and the question is, whether these distinct objects can be properly combined in one museum and by the same arrangement. If my own experience as a collector may be relied upon, this cannot be the case, unless an educational museum is collected from the first with a view to sequence, and unless this object is kept steadily in view whenever any addition is made to the collection, it will miss its aim. Take, for example, the case of the British Museum, which has accumulated from time to time by the accession of more or less homogeneous collections which have been purchased or presented, and which it is important to keep together. Out of any such collection it is probable that only a very few objects could be regarded as typical of any particular phase of development, say in pottery, sculpture, or glyptic art, and the remainder, although of the utmost value to the antiquary and necessary to be retained, would only serve to confuse any arrangement that might be made either for historic or educational purposes. Or take the case of a local museum in any large country town. Two distinct functions present themselves: on the one hand it is of use in preserving the antiquities or natural history specimens of the locality; on the other hand it should consist of general collections scientifically arranged and classified for the instruction of the people of the neighbourhood. We are brought by this to consider the advisability of having two distinct kinds of museums, which would bear pretty much the same relation to one another that a glossary of scientific terms would bear to a series of elementary treatises on different sciences—the one might be termed a museum of reference, the other an educational museum; the first arranged geographically, and the second having an evolutionary arrangement; the one special and the other general; the one arranged by finds and the other by subjects; the one comprising all the various objects that can be brought together from any particular district or country, and the other consisting only of such objects as may be selected as typical or as forming connecting links of development, the one composed exclusively of originals, and the other consisting in great part of casts, reproductions, and models. This provision, although I have placed it last in the list of distinctive functions, is by no means the least important in a practical point of view, because we see that by this means the two institutions ought never to be allowed to clash. Not only are reproductions and casts as useful as originals for the purposes of instruction, but models, in some cases, are infinitely preferable, because taking less room. Might it not serve to clear our ideas if we could arrive at the principle of utilising our existing institutions so as to serve the two distinct purposes above discussed, retaining the British Museum as a museum of reference, devoting South Kensington exclusively to the purposes of education and evolutionary arrangement, and separating the loan collections as a branch distinct from both. By this means we should be enabled to carry out the objects contemplated by Lord Wharncliffe's motion, not confining ourselves to statuary alone, but organising collections to illustrate the history of various other branches of art and industry, each commencing with the rude production of savage and prehistoric man, and ending with the complex contrivances of our own time. Each year the sums hitherto devoted to annual exhibitions would be applied to perfecting and re-arranging the collection, casting out some and replacing them by others more strictly representative in their character. The final result would be a museum of super-organic evolution worthy of the nation and of any labour that might be bestowed upon it. It might be thought, perhaps, that to carry out such a system representing any considerable number of arts and sciences, unbounded space would be requisite, but when it is remembered that the specimens would be rigidly confined to such as represented a distinct step of development, excluding all abnormal excrescences, it is evident that the number of objects required for any particular series would be limited.

My own collection of savage and prehistoric objects now exhibited at Bethnal Green has been collected upon this system during the last twenty years, and although the effectual carrying out of the plan has been limited by the means at my disposal, enough has been done to show that a considerable number of subjects may be represented without any extravagant demand on space. Weapons, pottery, early ship-building, personal ornament, carving and sculpture, musical instruments, early or savage drawings, clothing, early writing, objects illustrating the origin and use of fire, religious emblems, &c., are exhibited separately in cases occupying the basement on one side of the building, and several cases are devoted to the distribution and development of particular forms of ornament. The long rooms in the Exhibition buildings at South Kensington are admirably adapted for the extension of this system. Probably the best arrangement would be to devote the whole range of the side walls to objects laid out in historic sequence and to place in cases opposite each successive stage of art, objects belonging to existing peoples which correspond most nearly to the historic or prehistoric sequence on the opposite side; by this means both ancient and modern phases would be represented, and survivals where they occur could be traced to their sources.

A. LANE FOX

The Phonograph

IN reference to Prof. Mayer's account and Prof. Fleeming Jenkins's letters, I may say that I had an opportunity of an hour's observation of a phonograph constructed by Mr. Stroh, 42A, Hampstead Road, on April 3, at the invitation of Prof. Graham Bell. The difference between words produced from the phonograph and those spoken into it gave me the same feeling as the difference between a worn print and an early proof of an engraving. When the words were uttered loudly and slowly and repeated rather faster, it was easy to catch the sense and meaning, but I doubt whether unknown English words would be recognised, and certainly unknown foreign words would present insuperable difficulties. I should myself find the phonograph as at present constructed quite sufficient for my own purposes of registering pronunciation, especially delicate shades of dialectal utterance. Some words, as *see*, almost disappear. Both *ee* and *oo* are difficult vowels, so that Prof. Bell at first thought that the first sounded like the second, while in reality both are altered to indistinct sounds that I do not remember to have heard in speech. The resemblance is so great, however, that *bite*, *bout* could not be distinguished, though one ends nearly with *ee* and the other nearly with *oo*, and there is no other difference in the words. The vowels *ai*, *oa*, as in *bail*, *boat*, are also poor; *aa*, *au*, as in *baa*, *haul*, are really the only good ones. Hence I feel totally unable to speak positively as to the change of vowel quality by altering the rapidity of rotation and therefore pitch. As far as I could observe the quality did change, as it does in speech. We tried pronouncing words backwards, sometimes with good success, but as might be expected, even when the effects were recognisable, they were not always true. Thus, *aabaa*, *aadaa*, passed muster, but *aajaa* failed. The instrument is, however, not delicate enough to bring out these differences. The mechanical obstacle of the tin-foil, which has to be indented, and offers too much resistance, seems to be the cause of this. Such a word as *Scots*, when sung rapidly, at the beginning of *Scots wha hae*, degenerated almost into the simple vowel, the initial and final *s* were quite lost, and the action of the mutes, *c, t*, was almost *nil*.

The invention is highly interesting, the effects at present produced are sometimes startling (as in cries, coughs, laughter, music), the philosophy of the process (taking a permanent impression of a very complex compound vibration, and using it as a mould to reproduce that vibration) is exceedingly attractive, but at present the instrument—at least that one which I saw, differing in many respects from the one described by Prof. Mayer—has not risen beyond a lecture illustration or a philosophical toy. ALEXANDER J. ELLIS

April 13

Phoneidoscopic Representation of Vowels and Diphthongs

PERHAPS your correspondent, Mr. Sedley Taylor, would kindly test with his phoneidoscope the propriety of calling the English combinations *ea, ae, oe, ie* diphthongs, and the simple vowel *I*, as pronounced in the personal pronoun, a simple sound. Perhaps also the English *ā* (as in "*name*") may be regarded as a diphthong. In Otto's German Grammar, the German combinations *ae, oe, ue*, are classed as modified vowels. I fancy *oe* is a diphthong, though in rapid speech it becomes more like the simple sound *ue*. J. H. BLAKESLEY

Linden, Hannover, April 11

The Acoustical Properties of Soap Films.

IN connection with the interesting results recently obtained by Mr. Sedley Taylor upon the acoustic properties of soap-films, as exhibited in the simple and beautiful instrument which he has termed the Phoneidoscope, I should like to call attention to the following passage published in 1873 by Prof. E. Mach, of Prague, in his *Optisch-Akustische Versuche*:—

"Bei dieser Gelegenheit kann erwähnt werden, dass die Plateau'schen Flüssigkeitshäutchen sich vorzuglich zum Studium der Membranschwingungen eignen. Eine solche Flussigkeitshaut vor eine tönende Pfeife gebracht zeigt meist mehrere Bäuche. Ein Lichtpunkt, der sich in der Membran spiegelt, gibt mehrere glanzende geschlossene Curven."

After some remarks on the low tones to which these films vibrate, and on their vibrations to the upper partial tones, the author passes on to another subject with the remark:—"Ich erwähne diese Experimente, weil sie vielleicht, weiter verfolgt, zur Beantwortung mancher Fragen über Membranschwingungen beitragen können."

There is no mention, however, of the rotating pairs of coloured vortices noticed by Mr. Sedley Taylor. Brewster appears to have observed similar phenomena (see *Edin. Trans.*, vol. xxiv, "On Colours of Soap Bubbles," &c.) as the result of directed currents of air upon films. I have found that the vortices are also produced when a small lightly vibrating tuning-fork, having its prongs previously wetted with soap solution, is made to touch a flat soap film produced in the ordinary manner. SILVANUS P. THOMPSON

University College, Bristol, April 5

Cumulative Temperature

THE idea of a clock with an uncompensated pendulum for temperature integration referred to by Mr. Cooke (NATURE, vol. xvii. p. 323 and p. 448) has probably occurred to many persons, and was proposed by me in 1840; I found, however, that it was not new then. Forbes says in his Report on Meteorology (Brit. Assoc. Report, 1832, p. 213):—"A mechanical mode of taking the mean of an infinite number of temperatures has been proposed by M. Grassman, by observing the change of rate caused by the influence of temperature upon the uncompensated pendulum of a clock (*Poggendorff*, 1825). The idea is a good one, but was proposed long ago by Dr. Brewster ('Edinburgh Encyclopædia,' art. Atmospheric Clock)." The chief merit in this matter will belong to the person who puts the idea into a working form which can be proved capable of giving accurate results.

April 9 B.

The Southern Drought

IN response to your question appended to my letter in the last number of NATURE, I am able to give you the time of the last great drought in the Gilbert Islands. In 1870 I visit these and several other islands in the South Pacific (an a count of my cruise appeared in Dr. Petermann's *Mittheilung* for June, 1871), and at that time there was a very gener drought. I was among the Gilbert Islands during October, ar found that no rain had fallen there for several months. Tl cocoa-nut and pandanus-trees, upon which the people almo entirely depend for food, were very much dried up, and the fru upon them were small, both in quantity and in size. Th drought continued for two years after my visit, and the famir became so severe that many of the people were starved to deatl Had it not been for the fish they procured, it is doubtful whethe any of them would have survived, for the cocoa-nut and pandanu trees ceased to yield fruit, and the poor people were obliged t chew the roots of the trees.

Since that time I have heard of another season during whic there was little rain, in consequence of which there was com parative scarcity, but this was not to be compared with the grea drought of 1870-1872.

I regret to say no long-continued observations on the rainfa have been made in Samoa. My own time was so fully occupie with other matters, during my residence there, that I neglecte this one. As the droughts there have not been great enough t cause anything like distress, the periods of their occurrence have unfortunately, not been recorded. S. J. WHITMEE

Blackheath, April 5

Research in Libraries

BEFORE this "voice from Australia" can reach London, hope that some steps will have been taken towards carrying ou Dr. Mallet's valuable suggestion (NATURE, vol. xvi. p. 457) s far as regards the British Museum and other leading Europea libraries.

The benefit of the proposed arrangement would, I am sure be felt in Australia as much as in America. Anybody livin here, in the North of Queensland, who may wish to consult scientific book must take a sea voyage of 700 or 1,100 miles a a cost of 16*l*. or 20*l*. in money and at least a fortnight or thre weeks in time. It may happen that one has a busy friend i the library city who will undertake the search through good nature, but most people would prefer to employ a competen man who would do so as a matter of business.

Should the trustees or directors of the great libraries hesitat (and they may) to accept the responsibility of recommendin searchers, probably it would answer nearly as well if th searchers were to advertise references to well-known scientific o literary men. Perhaps a hint might be taken from the Registe House in Edinburgh. Titles to land in Scotland require registration for their completion. A purchaser, to satisfy himself that th seller has not previously alienated or burdened the subjects, has t overhaul the books of the register. This is done for him as a rul by professional searchers, some of whom are official and som unofficial. The system has worked admirably for some centurie I believe. Any Scotch lawyer could explain its details.

The subdivision of labour suggested by Dr. Mallet would enable a much higher use to be made of the system than th mere hunting-up of references. For example, if there were searcher in Paris—a well-read geologist—to whom I could intrust an order for "any references in French geographical works bearing on the date of the erosion of the terrace betwee the Queensland coast range and the Pacific," or some suc information, what possibilities would open out to the dwellers i distant isles, nay, even to the comparatively privileged inhabitant of London itself? ROBERT L. JACK

Geological Survey Office, Townsville, Queensland, Jan. 14

Mimicry in Birds

WITH reference to the correspondence on this subject which has recently apeared in NATURE, may I add the following instance, which has fallen under my own observation?—

On the coast of Kent is a tract of land protected from the sea by an embankment of shingle, and known as the "Reculve Marsh." It is frequented by skylarks and ring-plovers. Almost all these larks have incorporated the well-known alarm note of the plovers into their song. With such distinctness is this double note brought in, that the first time I heard it I could with diffi culty [illegible]ince myself that it was not uttered by *Ægialiti hiaticula*, In the surrounding district, where larks are equally numerous, I have never detected the peculiar note.

This power of imitating the songs of birds is well known to bird-fanciers and dealers; hence birds taken from the nest are considered worthless by those who admire the natural song. I myself had a Siskin that sang the goldfinch's song, and a nuthatch that I sent to a bird show came back with a wonderful medley of notes, of which he seemed extremely proud, the call-note of the canary and several notes of the blackbird being amongst those I could clearly recognise. J. YOUNG

Notting Hill

Harrow School Bathing Place

WILL you kindly allow me to appeal through your columns for suggestions how to cure a nuisance which we suffer from year after year in our bathing-place here, and for which we have as yet found no remedy?

The water which is pumped into the bath from a considerable depth is beautifully clear at the beginning of the season, but as soon as the weather becomes hot and the rays of the sun attain power, countless filaments, consisting of conferva, &c., spring up from the brick floor of the bath, and push their way rapidly to the surface, the depth of the water varying from about four feet to six feet. As the boys plunge from the side into the water and swim about the bath these long wavy stems are shivered into myriads of fragments, which collect on the surface of the water and form there a disagreeable and ugly scum, which detracts not a little from the pleasure of bathing during a great part of the summer term. We have taken some pains to discover a remedy for this, whether by chemical or other means, but as yet have been quite unsuccessful. The weed reappears in equal exuberance year after year and we are helpless. If any of your readers can contribute to the removal of this annual plague, he would confer a great benefit on the school, and any practical suggestions would be gratefully received either by G. Griffith, Esq., Harrow, or by ARTHUR G. WATSON

Harrow, April 8

London Clay Fossils

I SHOULD be glad if any of the contributors to NATURE would kindly inform me of any fossiliferous sections of the London clay at present open in the immediate neighbourhood of London. Many of those named in Whitaker's "Geology of London," such as Highgate, Hampstead Heath, &c., are closed, while others at Lewisham, &c., yield no fossils except a few fragments of wood. HERMANN H. HOFFERT

South Kensington Science Schools, April 15

Meteor

As the meteor of April 2 was seen at Ashwell, Herts, and with much the same course and splendour as observed at Leicester (but without any accompanying sound), it must have been very much further off than your Leicester correspondent imagines.

So bright a meteor, falling so early in the evening, cannot fail to have been much observed. H. GEORGE FORDHAM

Odsey Grange, Royston, Herts

The Nightingale

IN case you have received no earlier communication to a similar effect, you may possibly think it worth while to record that I heard a nightingale twice on the 14th instant, in a plantation by the side of Hanger Lane, in Ealing. It was but an abortive song, such as the first of the season is very apt to be, as if he were rather shy of the sound of his own voice. But there was enough of it to leave no possible doubt as to the identity of the performer. I may add that I have in previous years heard him in the same spot two or three days earlier than elsewhere in this neighbourhood.

I heard the wryneck ("cuckoo's mate") also several times on the same day in Gunnersbury and Hanger Lanes, having heard him once the previous afternoon (13th) in Kew Gardens.

Gunnersbury, April 16 G. J. PEARSE

FLOATING MAGNETS[1]

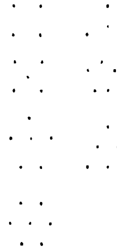
FOR one of my little books of the Experimental Science Series I have devised a system of experiments which illustrate the action of atomic forces, and the atomic arrangement in molecules, in so pleasing a manner that I think these experiments should be known to those interested in the study and teaching of physics.

A dozen or more of No. 5 or 6 sewing needles are magnetised with their points of the same polarity, say north. Each needle is run into a small cork, ¾ in. long and $\frac{3}{16}$ in. in diameter, which is of such size that it just floats the needle in an upright position. The eye end of the needle just comes through the top of the cork.

Float three of these vertical magnetic needles in a bowl of water, and then slowly bring down over them the N. pole of a rather large cylindrical magnet. The mutually repellent needles at once approach each other and finally arrange themselves at the vertices of an equilateral triangle, thus .·. . The needles come nearer together or go further away as the magnet above them approaches them or is removed from them. Vibrations of the magnet up and down cause the needles to vibrate, the triangle formed by them alternately increasing and diminishing in size.

On lifting the magnet vertically to a distance, the needles mutually repel and end by taking up positions at the vertices of a triangle inscribed to the bowl.

Four floating needles take these two forms.
Five „ „ „
Six „ „ „
Seven „ „ „



I have obtained the figures up to the combination of twenty floating needles. Some of these forms are stable; others are unstable, and are sent into the stable forms by vibration.

These experiments can be varied without end. It is certainly interesting to see the mutual effect of two or more vibrating systems, each ruled more or less by the motions of its own superposed magnet; to witness the deformations and decompositions of one molecular arrangement by the vibrations of a neighbouring group, to note the changes in form which take place when a larger magnet enters the combination, and to see the deformation of groups produced by the side action of a magnet placed near the bowl.

In the vertical lantern these exhibitions are suggestive of much thought to the student. Of course they are merely suggestions and illustrations of molecular actions and forms, for they exhibit only the results of actions in a plane; so the student should be careful how he draws conclusions from them as to the grouping and mutual actions of molecules in space.

I will here add that I use needles floating vertically and horizontally in water as delicate and mobile indicators of magnetic actions, such as the determination of the position of the poles in magnets, and the displacement of the lines of magnetic force during inductive action on plates of metal, at rest and in motion.

The vibratory motions in the lines of force in the Bell telephone have been studied from the motions of a needle (floating vertically under the pole of the magnet), caused by moving to and fro through determined distances, the thin iron plate in front of this magnet. These experiments are worth repeating by those who desire clearer conceptions of the manner of action of that remarkable instrument.

SUN-SPOTS AND TERRESTRIAL MAGNETISM

IN a remarkable article on "La Météorologie Cosmique," which has appeared in the *Annuaire* of the Bureau des Longitudes, for 1878, M. Faye says with reference to the influence of sunspots on the earth's magnetism, that the observations of Cassini "give 1787·25 for the date of the maximum observed then at Paris, whilst the latest observations—those of Mr. Broun, himself at Trevandrum—assign 1870·85 for the epoch of the last maximum. The interval is 83·60 years. On dividing this by 8, the number of periods in this interval, 10·45 years, are found for the duration of the period. That is to say, almost exactly the value already found by Lamont by means of his own observations at Munich. The period of the spots deduced by M. Wolf, 11·1 years, not being equal to that for the magnetic variations, these two phenomena have no relation to each other."

I desire to offer a remark on this conclusion, which seems to me too hasty. On examining the two periodic series, that for the diurnal variation of declination and that for the frequency of the solar spots, we see that there is a perfect coincidence in their phases though the length of successive periods is not constant. We may find a mean length of ten, eleven, or more years, according to the epoch from which the calculation is begun, but we shall always find the same length from both series if we commence at the same date.

It seems to me then that the true way to determine whether there is an intimate connection between the two phenomena is to compare their phases, and see whether the maxima and minima of the one coincide with those of the other. If there is identity in these respects, we must without doubt find the same mean values for the periods.

M. Faye accepts the date 1787·25 as that of a maximum for the oscillations of the declination. If we look then at the curve, Fig. 2, given by him in the article in question, we see that this corresponds exactly with a maximum of sun-spot frequency. In like manner similar coincidences are seen in the epochs deduced from the observations of Arago and others up to the present time when compared one by one with the sun-spot observations of Schwabe, Carrington, Secchi, as well as of those made at Kew. The conclusion seems to me very different from that of M. Faye. We are entitled to apply the rule he has given (p. 634): "If two series of phenomena, however different they may appear at first, follow exactly the same period, they ought to be referred to the same cause."

There is another passage upon which I desire to offer a remark: "Two kinds of meteors exercise a considerable influence on the direction of the magnetic needle, these are the auroræ boreales and the cyclones."

For the first there is a general agreement, but for the cyclones what observations have we which prove any such influence? If cyclones exercise a considerable influence on the direction of the needle, in what phase of the phenomenon does this occur? Is it on their formation, on their passage over some particular meridian, or when their centre is over a place? In the last case each cyclone will be a source of disturbance, which will be manifested as it progresses, and not simultaneously at all places, which, however, is what really occurs in the case of magnetic disturbances. Electricity is, without doubt, a cause, but only in the case of such considerable discharges as the aurora polaris; but not the local electricity which may accompany cyclones. When there is a storm, and the thunder rolls, and the electrometer shows enormous variations of atmospheric electricity, changing sign continually, the magnetic needle continues its usual and regular progress. Of this we can offer hundreds of examples.

JOAS CAPELLO

Lisbon, February 22

P.S.—The mean movements of the magnetic needle in the Lisbon Observatory, from eight A.M. to two P.M. are given in NATURE, vol. xiii. p. 448, for the years 1858 to 1875; the following are the corresponding mean ranges for the next two years:—

1876 ... ... 5·81′   1877 ... ... 5·54′

So that the mean movement was less in 1877 than in 1876.

OUR ASTRONOMICAL COLUMN

NEW COMPANION TO ALDEBARAN.—Mr. S. W. Burnham notifies his discovery with the 18½-inch Alvan Clark refractor of the Dearborn Observatory, of a minute star much nearer to Aldebaran than that which makes the double star H. VI. 66; he compares it with the ruddy bright star, as resembling, in difficulty and appearance, Mars and his outer satellite. The mean of three days' observations gives the angle 109°·0, and the distance 30″·35 for 1877·90, or if the second result which, as printed, differs nearly ten degrees from the other two, the angle will be 111°·9. The secular proper motion of Aldebaran, according to Mädler, is 19″·1 in the direction 157°; some years must elapse before the question of physical or optical duplicity can be decided. Eight days' measures of the close companion of Sirius, by Mr. Burnham, with the same instrument, assign for the angle of position 52°·4, distance 10″·83 at the epoch 1877·97.

THE STAR LALANDE 37813.—Mr. J. E. Gore writes from Ballisodare, Co. Sligo, with reference to this star, which appears in the reduced catalogue as a *second* magnitude, and which, observing in the Punjab in August, 1877, he had found a little less than Lacaille 8308 or 7 m. This is one of the errors in the catalogue which, as in a case recently noticed in this column, can only be cleared up by referring to the *Histoire Céleste*. The observation was made on August 20, 1795, and the star No. 37813 was really estimated 7·8 m. α Aquilæ was observed immediately before it, and entered 2 m.; it is this erroneous magnitude for the bright star of Aquila that has become attached to the star of which Mr. Gore writes. There is a very noticeable proper motion in N.P.D., apparently about + 0″·48 annually, as shown by comparison of the observations of Lacaille, Lalande, Jacob, and Argelander, with the position in the Washington Catalogue for 1860.

THE MINOR PLANETS.—Discoveries in this group still progress. No. 186 was detected by M. Prosper Henry at Paris, on April 6, shining as a star of 11·5 m., and No. 187 by M. Coggia at Marseilles, on April 10; it was estimated 10 m. No. 178 (Palisa, 1877, November 6) has been named *Belisana*, and No. 184 (Palisa, 1878, February 28) it is proposed to call *Deiopeia*. With already *seven* additions to the list, it would not appear that 1878 is likely to fall short of the most prolific of preceding years in these discoveries.

THE TRANSIT OF MERCURY ON MAY 6.—If we calculate strictly from Le Verrier's tables of sun and planet, using therefore the value of the sun's diameter which he deduced from the transits of Mercury in his memoir, printed as an addition to the *Connaissance des Temps* for 1848, we shall have the following formula for determining the time of the first *external* contact of limbs in the approaching transit:

t = [illegible] h. 13m. 1s. − [illegible] $r \sin l$ − [illegible] $r \cos l \cos (L - 56° 49'.)$

in which t is the Greenwich mean time of contact, r the radius of the earth at the place for which we are computing, *l* its geocentric latitude, and L the east longitude from Greenwich; the quantities within square brackets are logarithms.

At the Royal Observatory the first external contact is found to occur at 3h. 11m. 35s; the sun will set at 7h. 31m., about 30m. after least distance of centres, so that more than half the transit may be observed. At Edinburgh the first contact takes place at 2h. 58m. 53s. Edinburgh mean time, and the sun will set at 7h. 36m. The first *internal* contact at Greenwich and Edinburgh occurs 3m. 7s. later. The angle from North point of external contact is 45° towards East for direct image.

At Ogden, Utah, to which position it has been stated that a French Expedition is proceeding for the observation of the phenomenon, Mercury enters upon the sun's disc at 7h. 44m. A.M., and the egress takes place at 3h. 18m. P.M., the duration of the transit being 7h. 34m.

At the next transit at the descending node on May 10, 1891, the last external contact at Greenwich, according to Leverrier's tables, will occur at 4h. 50·4m. A.M., and as the sun will not rise till 4h. 10m., but little of the transit can be witnessed in this country. In the transit at the opposite node on November 10, 1894, the first contact of limbs appears to fall close upon sunset here. On November 7, 1881, as will be seen from the *Nautical Almanac*, the transit will be wholly invisible in England. It thus follows that on the afternoon of May 6 next, we shall have in these islands the only favourable opportunity of viewing the planet Mercury projected upon the sun's disc that is afforded during the present century.

GEOGRAPHICAL NOTES

AFRICA.—M. F. Deloncle, a member of the Geographical Society of Lyons, has recently translated into French a remarkably interesting itinerary of the voyages made by a Spanish friar in the middle of the fourteenth century. The work was originally written in the Catalonian dialect and devoted chiefly to travels in Africa.

The Society of Geography has prepared, for the Paris Exhibition, a map of Africa, measuring 2 m. × 2 metres, and showing the route of every explorer from 1754 to Stanley, in 1878. The number of travellers is 121, of whom not less than 42 are French; but a large number of these explored either Madagascar or the Desert round Algeria. The first name written in this list is Mayeur, a traveller now quite forgotten, who crossed the northern part of Madagascar.

NEW MEXICO.—During the season of 1877 a party of the U.S. Geographical and Geological Survey of the Territories, under the command of Lieut. C. C. Morrison, was detailed to survey the section of New Mexico lying between the 105th and 108th meridians and between the 33rd and 35th parallels, about half of which is mountainous, the rest being mesas and plains. In giving an account of their explorations at the last meeting of the Royal Geographical Society, Mr. T. W. Goad, the meteorologist of the party, mentioned some points in regard to the physical features and characteristics of the country surveyed, which attracted special notice. Between the Sierra Blanca and the Oscura Mountains a lava flow was met with of over seventy-five miles in length, with an average breadth of three miles. This Mal Païs, as the Mexicans call it, resembles a black river, widening and narrowing as the country undulates. This stretch of lava, owing to denudation, is somewhat higher than the surrounding country, and is full of caverns. Several of these were visited by the survey party, but the only one of importance was near Fort Stanton, which, like the others, was in a limestone formation, and proved of considerable length; some persons, indeed, asserted that no one had been to the end, though a distance of five miles was measured. The exploration of this cave was of a most uncomfortable nature, necessitating long crawls through narrow passages, and obliging the explorers to wade up to their waists in ice-cold water for hours. Stalactites and stalagmites of immense size were met with. The lake in the cave was said to contain eyeless fish, but none of the party were able to catch or see any. The cañon, again, of the Rio Grande, below Castilla, is of peculiar interest, because it differs in most respects from other cañons, and instead of being worn away by the action of the water alone, it was probably commenced by volcanic action. The sides are of trap-rock, and although the cañon itself is very narrow, its depth was estimated at 1,000 feet. The river at this point has a great fall and rushes along with a velocity of ten miles an hour. Mr. Goad describes the climate of New Mexico as delightful.

GEOGRAPHICAL ANNUAL.—The new volume of *L'Année Géographique*, for 1876, has at length appeared. The delay has been caused by the resignation of the editorship by M. Vivien de St. Martin, whose time is now so fully occupied with other work. The new editors are MM. Maunoir and Duveyrier, and the new volume is quite up to its predecessors. The volume for 1877 will be published about June.

METEOROLOGICAL NOTES

METEOROLOGY OF STONYHURST.—The results of the meteorological and magnetical observations at Stonyhurst for 1877 are already published. In addition to the very full statement of the results for the year, and which are compared with the averages of previous years brought down to date, there are given observations of crops, flowers, trees, and shrubs; observations of the cirrus clouds made at the observatory in connection with Prof. Hildebrandsson's large inquiry into the upper movements of the atmosphere; and a discussion of the hours of occurrence of the barometric maxima and minima during the eight years ending 1875. This discussion has been evidently conducted with great care and with full knowledge of the subject in hand. The results arrived at are of great importance, the chief points being that there is a tendency of the maxima to occur between 10 and 11 A.M. and P.M., the total number from midnight to noon being, however, considerably in excess of that from noon to midnight; and that the minima occur with nearly the same regularity as the maxima, but at different hours, viz., about 3 and 4 A.M. and P.M. The importance of these results lies chiefly in the circumstance that they accord with the hours of the critical phases of the diurnal fluctuations of the barometer, and peculiarly so as regards the annual results. We are much pleased to see from the report that Father Perry is engaged with the discussion of the meteorological observations made at Kerguelen during the Transit of Venus Expedition, to the results of which meteorologists will eagerly look forward.

WEEKLY STATISTICS OF THE WEATHER.—The Meteorological Office has begun to issue weekly statistics of the weather of the British Islands for agricultural and sanitary purposes. For this object the country is divided into two divisions, the one being suited for the production of wheat, and the other for the rearing of stock. For each of the ten regions into which these two divisions are sub-divided there are published the highest, the lowest, and the mean temperature of the week, and the degree to which the last is above or below the average of the week, together with the number of days of rainfall, its amount, and the difference between the latter and the average rainfall of the week. To these follow general remarks on the weather as regards frost, winds, storms, and any irregularity that may have occurred in the rainfall at the selected stations. This step is in the right direction, and the scheme will no doubt soon receive greater extension and further development in order that it may the fuller meet the requirements of the classes for which it is intended. It is desirable, for instance, if not indeed essential, that the mean temperature be given to tenths of a degree and not merely to whole degrees, particularly when it is kept in view that no inconsiderable portion of Great Britain is but little removed from the limits of the successful cultivation of the wheat, and the rainfall to hundredths of an inch, so as to mark off clearly the practically rainless districts during each week. The number of stations situated on the coast preponderates too largely. Additional stations from several of the great agricultural centres are needed, and a partition of the country into more districts than ten, it being evident that a division of Scotland merely into east and west, and of Ireland into north and south, is inadequate. Scotland, for instance, should be divided at least into north-east, north-west, south-east, and south-west divisions, these differing essentially from each other in their climatic and agricultural peculiarities.

Missouri Weather Reports, Nos. 1, 2, and 3.—The system of weather service for the State of Missouri is being satisfactorily and energetically developed by Prof. Francis E. Nipher, Washington University, St. Louis. The second report, being for January last, is accompanied with a table showing the rainfall at thirty-eight stations in Missouri and a map on which the amounts are entered and isohyetal lines drawn showing where the fall was nothing, one inch, two inches, and three inches respectively. From this map the distribution of the rainfall, a correct knowledge of which is so important to farmers and others, is seen at a glance. The distribution of the heavy snowfall of the 30th and 31st is particularly detailed, and we are pleased to see the frankness with which Prof. Nipher informs his observers that it has been impossible to give a proper account of the remarkable storm of the 26th, which entered the northern part of the state at 8 A.M. and soon thereafter developed into a severe thunderstorm in central and southern Missouri, owing to the times of the beginning and ending of the storm not being given carefully for a sufficient number of places. We feel assured that the observers will gladly see to the rectification of this and supply the information desiderated in future. From the first report we see that the mean temperature of December was 12°·4 above the average of the month; and with this high temperature, the mean of the month being 45°·6, vegetable and animal life was prematurely urged forward at an undesirably rapid rate. A valuable table accompanies this number, which has been prepared by Dr. Engelmann, giving the mean monthly temperatures and extremes and the mean rainfall at St. Louis for forty-two years, from which it appears that the mean of the coldest month, January, is 31°·7; the warmest month, July, 79°·2, and of the year, 55°·4. The highest temperature noted during these forty-two years was 104°·0 in July, 1860, and the lowest—23°·0 (below zero) in January, 1873. The mean annual rainfall is 42·46 inches, the largest monthly fall being 5·39 inches in June, and the least, 2·13 inches in January.

Extraordinary Rain-Storm in Canada.—A continuous storm of rain, extending over two or three days, and covering a considerable portion of North America, occurred in the end of February, the weather for some time before having been unusually mild. Near the coast rain prevailed, in the Quebec district much snow fell, about Ottawa, sleet, hail, rain, and snow fell in succession, and on advancing westwards through Canada, and into the United States, the precipitation appears to have been heavier. In Central Canada the floods seem to have been most destructive, and immense damage has been done to the towns built on the rivers, by the loosening of the ice by the floods, which, floating down the swollen rivers, carried bridges and other structures before it. Much damage was also done by the ice running aground at various points, and thereby damming up the rivers, by which extensive stretches of low-lying grounds were submerged.

Comparative Atmospheric Pressure of New Zealand and Great Britain.—Mr. C. Rous Marten, whose name has been so long and so favourably associated with the meteorology of New Zealand, has published a short paper on this subject in the *Transactions* of the Wellington Philosophical Society. The mean pressure of the atmosphere of Great Britain calculated from fourteen stations distributed from the Channel to the Moray Frith, is 29·848 inches; and of New Zealand, as similarly determined from fourteen stations from Southland to Mongonui, 29·918 inches. The interest of the comparison lies in this, that pressure diminishes in both countries at a somewhat rapid rate on proceeding into higher latitudes, and that though the New Zealand stations lie on the average in about 12° lower latitudes than British stations, yet the pressure does not greatly differ in the two countries. The strong resemblances between the climatologies of the two countries result from the peculiar distribution of pressure common to both and the lie of their mountain ranges, by which the prevailing winds are westerly, and being laden with the vapour of the ocean they have traversed, are productive of rainy climates in the west, and dry climates in the east.

NOTES

Invitations have recently been issued by the Rector of the University of Pavia to the various scientific societies of Europe, to participate in the ceremonies connected with the unveiling of the statue of Volta on April 28.

The Electro-metallurgical Company of Brussels has lately completed a colossal statue of Jan van Eyck, in bronze, by the system of electric deposition. The galvanic process occupied several months, although a thickness of but six to eight millimetres was attained. It is probably the largest object which has been produced by this method, being over twelve feet in height, and is regarded as a much more perfect imitation of the model than could be obtained by casting.

The meeting of the delegates of the French Sociétés Savantes will take place as usual at the Sorbonne, in the first week after Easter. M. Bardoux will preside over the meeting for the distribution of prizes, and deliver an address summarising all the measures contemplated by the Government for promoting popular instruction.

M. Bardoux has given the decoration of the Legion of Honour to the oldest schoolmaster of France, who has been teaching since 1818 in the very parish where he was born. The ceremony took place at Clermont-Ferrand at a dinner given by the Prefect in honour of the Minister. The whole scene is said to have been very impressive.

M. Asseline, a journalist and a member of the Municipal Council of Paris, died suddenly a week ago. He was one of the Society of Mutual Autopsy recently established in Paris for investigating by *post mortem* examination all the circumstances of death, and his case was the first instance of the application of the rules of the Society. The autopsy was made by Dr. Broca, the president of the Society, and the results published in the papers.

The Municipal Council of Paris has appointed a Commission of ten members in order to take part in the proceedings of the French Association for the Advancement of Science, which will take place at Paris, as we have already reported. They will sit in their official capacity.

A Société de Minéralogie has been formed in Paris, with M. D[illegible]Cloiseaux as president. It meets on the second Tuesday of each month in the mineralogical laboratory of the Sorbonne, A *Cours Annexe* has been created at the Sorbonne for physical astronomy. M. Wolff will lecture on the observational methods of physical astronomy, and the constitution of celestial bodies.

M. OSSIAN BONNET, Director of Studies to the Polytechnic School, has been appointed successor to M. Leverrier in his capacity of Lecturer on Mathematical Astronomy.

THE Italian Cryptogamic Society, founded in 1858 by De Notaris, has just been reconstituted under the presidency of Prof. F. Ardissone, of Milan. It consists of two classes of members: ordinary (*effettivi*) and foreign. The former consist entirely of Italian, the latter of foreign cryptogamic botanists, the foreign members being elected by the vote of the ordinary members. The Society will publish annual volumes of its "atti," and, in addition, one or more fasciculi every year, each containing fifty new or interesting species of cryptogams, at a cost of 10 lire (Italian) the fasciculus. The British corresponding members at present are the Rev. M. J. Berkeley, Dr. R. Braithwaite, Dr. M. C. Cooke, Mr. Jas. Stirton, and Mr. John Smith. Cryptogamists who are not members of the Society are invited to contribute descriptions or specimens of new species, for which they will receive in exchange the volume or fasciculus containing their contributions.

THE Birmingham Natural History and Microscopical Society, one of the most active of our provincial societies, have resolved to spend about 100*l*. in improving and adding to their apparatus.

THE Faculty of Medicine at Lyons has taken the initiative in a subscription for the erection of a monument to the late Claude Bernard on the Quai de la Vitriolerie.

DR PULUJ, of Vienna, exhibited at a recent session of the Imperial Academy, an ingenious arrangement for signalling by means of the telephone. The vibrating membranes in two connected telephones are replaced by a pair of tuning-forks giving the same number of vibrations per second. A bell is placed close to each fork and a brass ball is suspended from a thread between the two, but in contact with the fork. If one of the forks be put in vibration by means of a hammer the movement is communicated to the other, which causes a loud ringing on the bell by means of the ball. A response can be sent back in the same manner, and after replacing the vibrating membranes, the usual method of communication begins.

A FRENCH inventor, M. Brégnet, has recently completed a so-called mercury telephone, which is quite a variation on the systems already in use. It is composed of two instruments for transmission and reception, connected by means of wires. Each of these consists of a glass vessel, containing acidulated water and mercury, into which is inserted a capillary tube filled with mercury. One wire connects the mercury in the tubes, and the other that in the vessels. When a person speaks before the transmitter, the vibrations of the air are communicated to the mercury, and cause variations in the electromotive force, which are transmitted to the receiver, and there give rise to vibrations of the air appreciable by the ear. A later simplification of the apparatus consists in using a tube with alternate drops of mercury and acidulated water, forming thus a series of electro-capillary elements.

WE are glad to know that one of the signs of our times is a more appreciative and intelligent interest in the things lying around us, including the beauties of nature as well as those affairs of a more human interest. Messrs. Marcus Ward and Co., in their new monthly publication, entitled, *Our Native Land*, a copy of which we have just received, certainly deserve well of those who think that the habit of observation can be fostered and developed by calling attention to the many things of beauty and interest in our own country. The work is to consist of reproductions of water-colour sketches, with descriptive notes, and the publication breaks ground by giving coloured plates and text illustrating "Derwentwater," "Ambleside," and "Rydal Falls." The publication is as excellent in execution as it is admirable in idea, and the reproduction of the water-colour of Ambleside is admirable; it is one of the finest specimens of chromolithography that we have ever seen. Its truth to the colour of nature and the softness of the atmospheric effects, leaves little, if anything, to be desired.

MACMILLAN AND CO. are preparing for publication a "Journal of a Tour in Morocco in 1871, including a Visit to the Great Atlas," by Sir J. D. Hooker, P.R.S., &c., and John Ball, F.R.S., with a Sketch of the Geology of Morocco, by George Maw, F.G.S. The work will be illustrated by Mr. Whymper.

GEN. DE NANSOUTY, the director of the Pic du Midi Observatory, has been appointed Officer of Public Instruction as a reward for his efforts and successes. He had already been made, eighteen months ago, Officer of the Academy. The General Council of Vaucluse framed, at its last session, a resolution for establishing a meteorological observatory on the top of Mount Ventoux, a mountain about 2,000 metres high, situated in the most admirable position for an extensive view of an immense region.

THE intellectual abilities of the Japanese race have been evidenced in a striking manner by a quartette of students from that country now studying in Berlin. One of these, Dr. Dirokitao, has lately invented an ingenious optical instrument termed the leucoscope, which measures the variations in the perception of light and colour by the human eye, in accordance with the strictest mathematical laws. Another, who has attained the rank of lieutenant in the Prussian army, has introduced a remarkable simplification into the mechanism of the Mauser rifle, which has succeeded the historic needle-gun. Two more who are prosecuting their chemical studies under Prof. Hofmann, have published for two years past several interesting synthetical researches on the aromatic series.

THE canvas for the great Paris captive balloon is quite ready; it forms 46 rolls, weighing 60 kilogs. each, having a length of 80 metres, and a breadth of 113 centimetres. It was submitted to a traction of 1,000 kilogs., under which it has extended 25 millimetres per metre. After some time the increase in length was reduced to 12½ millimetres. The net is almost finished. It is composed of 256 ropes 11 millimetres each in diameter, and bearing a strain of 1 ton.

IN a note in the *Bulletin* of the French Scientific Association, Col. Gazan gives some interesting observations on the fracture of iron. During his sojourn in the arm manufactories of St. Etienne and Tulle, at the central depôt of artillery, and at the manufactory of Châtellerault, he was able to make important researches on iron. The fracture of iron may be nervous, in grains more or less fine, or in facets sometimes having a surface of several square millimetres; often it presents a mixture of these three features. Thus it is impossible to judge of the quality of an iron before breaking it; and it is on this account that in arm manufactories they break a certain number of bars with which they make a certain number of pieces for which they are intended, and which are afterward broken to ascertain their resistance, that is, the goodness of the iron, which, moreover, is still rendered brittle in presence of phosphorus, arsenic, or sulphur. The best irons are the nervous, then those of fine grain and with facets. On railways it has been proved that rails placed in the direction of the magnetic meridian are affected quite differently from rails placed at right angles to this direction; the former oxidise and do not become brittle, the latter do not oxidise, but do become brittle. In intermediate directions the rails participate more or less in the qualities of those which are placed in the two extreme directions. What becomes of the iron which is now so plentifully used in the construction of building—girders among others? Is not this a subject for serious research?

THE French Minister for Public Works has accepted the plans of an underground railway in Paris, which was worked out by order of the Prefect of the Seine. According to these it is intended to build the central station seven metres underneath the gardens of the Palais Royal. Three different lines will radiate from that spot, viz.: (1) to the Exchange, the Opera, the railway station of St. Lazare, then to Batignolles, communicating with the Great Western Railway and the Chemin de Fer de Ceinture; (2) to Les Halles, the rue Turbigo, the Boulevard Sebastopol, the Boulevard de Strasbourg, the Great Eastern and Great Northern Railways; from the Boulevard de Strasbourg a branch line would lead to the Vincennes and Lyons Railway Stations, passing underneath the Seine to the left bank of the river; (3) to the rue de Rennes, the Montparnasse Railway Station, the station for Sceaux, and to Gentilly. The cost of the lines is estimated at 6,000,000*l.*, and is to be borne jointly by the State, the Departement de la Seine, and the City of Paris.

WRITING in *La Nature*, M. Hélène calls attention to the excellent example set by Switzerland in regard to popular meteorology. There is hardly a town but has in one of its squares, perhaps at the side of a lake, an elegant column with instruments required for observation of the usual phenomena. Thus in Fribourg, is a black marble column (about 2·65 m. high) on a granite platform. On the north face is an alcohol thermometer, with double graduation cut in the marble; on the west a mercury barometer; on the east a hair hygrometer. The south face has an inscription giving the longitude, latitude, altitude, barometric and thermometric means, and annual rainfall. On a globe crowning the column are lines giving the direction of the four cardinal points. An inscription near the base tells that the column was erected by the Fribourg Society of Natural Sciences. The monument cost not more than 1,500 to 2,000 francs. Such columns often give various other kinds of information, *e.g.* the hour in different cities of the globe when it is midday at Berne, the heights of neighbouring mountains, measures, variations of lake level, records of severe winters, &c., in short the chief points which a natural curiosity would seek knowledge of. They are generally erected by cantonal societies.

WE have received the first two parts of the tenth edition of Cooley's "Cyclopædia of Practical Receipts," revised and partly rewritten by Prof. R. V. Tuson, F.C.S. To what extent the work has been brought up to date may be learned by looking at the articles on Spectrum Analysis and Anemometers; in the latter case the anemometers now in use are dismissed in a foot-note.

INTERESTING antiquities, coins, vases, &c., have recently been found at Strassburg in some excavations which are being made in connection with water-works. In some parts a number of skeletons of animals have been discovered, amongst others a well-preserved jaw with tusks of a prehistoric boar, and some deer horns, &c.

AT Cologne a meeting of the International Society against the pollution of rivers, the soil, and air, took place a few weeks ago. Its reports are published by Herr Hugo Voigt, at Leipzig.

THE International Congress for the investigation of the history of America before Columbus, will meet at Brussels during 1879. Originally it was intended to hold the meeting at some American city.

THE United States of North America possessed only forty-nine public libraries in the year 1800. The number has now risen to no less than 3,682, and the number of volumes contained in them exceeds thirteen millions.

TWO new institutions are about to be established in Germany; one at Bielefeld, for textile industries, and another at Iserlohn, for metal industry.

ON March 11 the Ural Mountains were first crossed by a railway train upon the occasion of the opening of the new line from Perm to Jekaterinburg.

ON the 14th inst. the Institution for the Deaf and Dumb at Leipzig celebrated the 100th anniversary of its foundation. It is the oldest institution of the kind in Germany.

A NEW eruption is reported to have occurred in Iceland on March 24, in the vicinity of Mount Hecla.

DURING the past three years Admiral Duperré has met with considerable success in his efforts to develop the resources of the French colony in Cochin China. He first started an experimental farm just outside Saigon, where sugar-cane, cotton, indigo, coffee shrubs, &c., were planted under the superintendence of a botanist from Paris. From this farm thousands of coffee plants, &c., are distributed every year all over the colony among the French and native planters. Tobacco has also been successfully cultivated, and attempts are about to be made to prepare the leaf for the European market, and an official from the tobacco manufactory at Paris has been appointed to superintend this work. The sugar-cane is found to flourish well in Cochin China, and experiments are being made with a view to discovering the best means of turning it to profitable account.

AT p. 16, vol. xvi. of NATURE, is an account of a new stimulant known as pitury, which it was shown had been proved by Baron von Mueller to be derived from *Duboisia hopwoodi*, a plant described by himself in 1861. It was mentioned in the paper above alluded to that the better known species of *Duboisia*, namely, *D. myoporoides* of Robert Brown might possibly prove to be of some medicinal value. This prophecy has since been borne out, for in a paper read by Dr. J. Bancroft on Duboisia and Pituri before the Queensland Philosophical Society at Brisbane, a good deal of information is given on both these new medicinal products. With regard to *D. myoporoides*, which is a small tree or shrub, we are told that it is found in various localities from the neighbourhood of Sydney to that of Cape York, and that it has also been found in New Caledonia and New Guinea. It grows plentifully on the borders of the vine scrubs about Brisbane and springs up abundantly after the clearance of forest land. The valuable part of the plant seems to be the leaves, from which an extract was, in the first place, made, and its effects tried upon some cats and dogs, which, during the time they were under its influence, were as helpless as if they were totally blind, falling down when the slightest obstacle came in their way. A trial of its effect was afterwards made on the human eye in several cases, and its action in dilating the pupil was found to be very powerful and rapid. The active principle seems to be almost identical with atropine, both as regards its action and its strength, and it is used in Sydney and Brisbane in place of that alkaloid. A good deal of attention has been given in this country to the new agent by Dr. Ringer and Mr. Tweedy. The former says that it has the power of drying the mouth or preventing the flow of saliva, and that it also produces headache and drowsiness, while the latter considers it quicker and more energetic in its action than atropine, and considerably more so than the strongest extract of belladonna. In every case in which it had been used by him he found its action entirely satisfactory. This subject, which is one of importance, inasmuch as it promises to open up a new source of supply of a substance fully as efficacious as, or perhaps more so than, atropine or belladonna, has for some time past attracted much attention in the colony where the plant grows, and has quite recently been brought to the notice of the Pharmaceutical Society. It is perhaps worth noting, that one of the colonial names of *Duboisia myoporoides* is the cork wood tree, so named from its light brown corky bark. The wood is of a light yellow colour, even grained, but soft, and used in the colony for carving. Specimens of the wood are contained in the Kew Museum.

THE additions to the Zoological Society's Gardens during the past week include an Arabian Baboon (*Cynocephalus hamadryas*) from Arabia, presented by Dr. A. P. Woodforde; two Chacma Baboons (*Cynocephalus porcarius*) from South Africa, presented by Capt. W. L. Coke; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. Milward; a Great Kangaroo (*Macropus giganteus*), a Laughing Kingfisher (*Dacelo gigantea*) from Australia, presented by Lieut. Crawford Caffin, R.N.; a Short-eared Owl (*Otus brachyotus*), European, presented by Mr. W. K. Stanley; a Golden-winged Parrakeet (*Brotogerys chrysoptera*) from the Amazons, received in exchange; a South American Rat Snake (*Spilotes variabilis*) from South America, deposited; a Yellow-footed Rock Kangaroo (*Petrogale xanthopus*), born in the Gardens.

THE DETERIORATION OF OIL PAINTINGS[1]

OIL paintings are subject to various kinds of changes, which may be considered as diseases, requiring different treatment according to their different nature. A science needs to be formed, a pathology and therapeutics of oil paintings. The pathology would have to describe and explain those diseases and their progress, and to develop the methods by which a correct diagnosis could be arrived at in each individual case. The therapeutics would teach the remedies which might be applied either to cure or to alleviate the disease, or at least to stop its progress. A hygiene would follow, which would have to teach how to avoid pernicious influences, and which, besides, while giving precepts for the technical process of painting, would have to forestall those constitutional diseases which, even in cases where no noxious influences can be traced, are the causes of decay, after a comparatively short period of existence. As medical science is above all things based on anatomy and physiology, so the exact knowledge of the structure of a picture would have to be acquired previously to any study of its disease. Unfortunately, direct investigation alone can procure no such exact knowledge; on the contrary, we are obliged to enter upon a minute historical investigation of the material as well as of the technical methods adopted by artists of different schools and different periods.

The excellent works of Cennino Cennini, Merimée, Sir Charles Eastlake, Mrs. Merrifield, and others, have already furnished most valuable material; but still the field for investigation remains unlimited; for, in order to enable us to secure the conservation of each valuable painting, we ought to know exactly how it was made. The artists of the present time would spare infinite trouble to the investigators of future times, if, along with their works, they would leave the account of their practice in the case of each picture. A treatment without exact knowledge of the normal condition, as well as of the nature of the disease, is, as we shall see, as dangerous for the picture as it would be in the case of living beings.

Professional restorers of pictures admit this danger in a general way; each of them, however, is convinced that he himself, by his personal knowledge, skill, and care, knows how to avoid it. The public pays too little attention to the subject, and therefore it occurred to me that it might be useful to give a short account of what we know about this question, of the changes to which oil paintings are exposed, as well as of the means either to avoid or to cure them.

We have to consider, first, the material on which the artist has painted, that is, as far as oil painting is concerned, principally wood and canvas.

Secondly, the priming, that is, the substance with which the surface was prepared in order to be made fit for painting.

Thirdly, the painting itself, that is, the pigments and vehicles used for it, and the liquids that were added during the painting, the mediums, meguilp, siccatire, varnish, essential oils, &c.

Fourthly, the coat or coats of varnish spread over the picture.

The wood on which a picture has been painted may either warp, or get chinks in it, or become worm-eaten, or even altogether rotten. Against warping, the remedy usually applied is moisture. If the panel is very thick, it is first made somewhat thinner; then the back is moistened, and the picture is left to lie on its back for twelve to twenty-four hours, after which time it will be found to have bent straight. Of course this must not be continued longer than necessary, otherwise the convex surface, instead of becoming plane, would become concave. When straight, the picture is kept so by beads which have to be adapted in a particular way, a certain degree of shifting being allowed for the expansion and contraction of the wood.

Cracks in the wood are drawn together by inserting pieces of wood of a special shape.

Sublimate solutions are employed to destroy worms.

Trifling losses of substance are replaced by cement. Small portions of rotten wood, not extending too near the painting, are cut out and replaced by wedge-shaped pieces. If, however, the greater part, or the whole substance of the panel, is rotten, the picture must be separated from it and transferred to new wood, or rather to canvas.

This was first tried by Hacquin in Paris, and was performed successfully upon many pictures, and, among others, upon one of Raphael's Madonnas, in the Gallery du Louvre, and upon Sebastian del Piombo's "Resurrection of Lazarus," now in the National Gallery. The process no longer appears so very marvellous; it is generally executed in the following way:—

First of all, the surface of the picture is pasted over with gauze and paper. After that the wood is made straight by moistening, or, if necessary, by making incisions with the saw, into which cuneiform pieces of wood are driven. By means of a tenon-saw the panel is to be sawn into little squares, which must be removed by a chisel, and in this way the thickness of the wood is reduced to half an inch; it is then planed until it becomes no thicker than paper, and the rest is removed by means of a knife and with the fingers. The painting being thus severed from its basis, it can be fixed on canvas, if the priming is sufficiently preserved. In the opposite case, a mixture made of chalk and glue, or something of the kind, must be put on first, and very evenly smoothed, after being dry. This done, the new canvas has to be fixed upon it by means of a mixture of glue, varnish, and turpentine, and the substance of the picture pressed tightly and evenly against it by means of warm irons.

In order to avoid deterioration, the most minute precepts have been given for preparing the panel. It has to be taken from the best oak, or nut-trees, or cedars. The wood is to be cut into boards during winter-time, and kept till autumn before being dried; it can then be prepared only in the following spring, &c. It would certainly be preferable to give up wood panels altogether for large pictures, and only to think of means to make the canvas stronger. For small pictures, panels offer certain advantages, and can be more easily preserved from decay.

In the canvas we meet with the results of injuries or spontaneous decay. A rent may be mended by rags of linen stuck at the back of the picture. Even a hole may be filled up by pieces taken from other decayed paintings. If the picture is considerably damaged, it will be best to line it. But if the whole canvas is rotten and tattered, it will be preferable to sacrifice it by pulling off the threads one by one, after having secured the painting itself by pasting paper on the front of it. This done, the painting is transferred to another canvas in the same way as those removed from wood.

There are different modes of priming, which may be brought under two principal heads: the distemper and the oil priming.

1. The canvas is distempered by a mixture of chalk or plaster and paste, or glue, which may be laid on raw, unbleached canvas, or this latter may be beforehand prepared with glue or paste. Several coats of this mixture must be put on in succession, one being perfectly dry before the next can be applied. Many of the older oil paintings are painted on such ground. It has the advantage of being quicker prepared, of absorbing the excess of oil, of permitting the colour to enter into the

---

[1] Paper read at the Royal Institution, Friday, March 1, by R. Liebreich M.D., M.R.C.S., M.R.I.

priming, and to dry quicker, and moreover, of containing a white absolutely innocuous to the others.

The inconveniences, on the other hand, are: that it more easily breaks, and under the influence of humidity separates from the canvas.

2. The oil priming consists of several coats of oil colours. As each of these must be perfectly dry before the next is laid on, and as, moreover, time must be given to the whole to dry completely before painting upon, in order to avoid the sinking in of the colours, the whole preparation is much slower than the distemper. Nevertheless it is now generally adopted.

Rey, in France, has pointed out a process which is a compromise between the two methods; he begins by distempering, and after several coats of distemper, having dried one after the other, he puts a coat of oil which, as it were, changes the distempered ground into an oil-colour ground.

With oil priming it is of importance that the principal colour be white-lead, to which are added comparatively small quantities of yellow, black, or other colours. For a whole century a school, that of Bologna, predominated in Italy, which abandoned this principle. During the second half of the seventeenth and the first half of the eighteenth century, most of the Italian masters of other schools followed its example. Probably for the purpose of obtaining more easily the desired effect of the chiaroscuro, they painted on a brownish-red priming, which consisted of bolus mixed with umber. Not one of those pictures has kept its original colouring. Not only has the priming caused all the dark parts to grow much darker, but it has destroyed, or nearly so, all the glazing, so that only those colours can be recognised which either contain white, or are glazed on white. I can show you numerous instances of this, for, on account of the extreme fertility of this school, there is little difficulty in procuring pictures of masters of that time or of their pupils.

Wood priming does not require the same elasticity as that of the canvas, which ought to be capable of being rolled. Therefore the priming of the wood shows less variations. It is generally composed of chalk or plaster, tempered with starch, paste, size, or glue, and more or less thickly laid on. In some pictures of different centuries we find, either between the wood and the priming, or between the priming and the painting, canvas, and, exceptionally, even paper.

The diseases of the priming are not of a very complicated nature. They manifest themselves principally in three different ways:—1. By cracks in the priming itself. 2. By the severance of the priming from the painting. 3. By the severance of the priming from the wood or the canvas. The third disease is by far the most frequent, especially among pictures on canvas distempered with paste. If small pieces only are scaling off or blistering, they are fixed again to the ground by letting a solution of size pass between the detached part and the canvas, and pressing both gently together. If the deterioration extends over a considerable surface, the picture has to be lined. While this is being done, and while the gluing substance penetrates into the picture, the detached parts are pressed on again with slightly heated irons. If the whole priming threatens to come off, it will be better to take the picture entirely from the panel or canvas, and to transfer it to a new canvas.

I shall show you examples illustrating the before-mentioned points, and among them two pictures; one in oil, taken off from canvas, the other in tempera, taken off from wood. Both of them, strange to say, have escaped destruction without having been transferred to a new canvas, and without being covered with paper, as is usually done, before taking them off. They show you the painting by itself from both sides. I have, of course, used every precaution in bringing them safely over from Florence, where I happened to discover them carelessly stowed away among heaps of old pictures.

We come now to the most important part of the picture, the painting itself. We meet very often with the idea that the old masters had been in possession of colours, that is pigments, the knowledge of which has been lost, and that this accounts principally for the difference between the oil painting of the fifteenth and sixteenth centuries, on the one hand, and that of the eighteenth and nineteenth on the other. But this is a great mistake. We know perfectly well the pigments used by the old masters; we possess the same, and a considerable number of new ones, good as well as bad, in addition. In using the expression of good and bad I am principally thinking of their durability. From this point of view the pigments can be placed under three headings:—

1. Those which are durable in themselves, and also agree well with the other pigments with which they have to be mixed.

2. Such as when sufficiently isolated remain unaltered; but when in contact with certain other pigments change colour, or alter the others, or produce a reciprocal modification.

3. Those which are so little durable that, even when isolated from other pigments, the mere contact of the vehicle, the air, or the light, makes them in time fade, darken, or disappear altogether.

The old masters used, without reserve, only those belonging to the first of these categories. For those belonging to the second they imposed on themselves certain limits and precautions. Those belonging to the third they did not use at all.

That some of the modern masters have not followed these principles is not owing to a lost secret, but to the fact that they disregarded those well-known principles, and even consciously acted against them. In Sir Joshua Reynolds's diary, for instance, we read that in order to produce certain tints of flesh, he mixed orpiment, carmine-lake, and blue-black altogether. Now orpiment is one of the colours of the second category, carmine-lake one of the third. That is to say: orpiment, as long as it remains isolated, keeps its brilliant yellow or reddish-orange colour; but when mixed with white-lead it decomposes, because it consists of sulphur and arsenic, and it, moreover, blackens the white-lead, because the sulphur combines with it. Carmine-lake, even if left isolated, does not stand as an oil colour, and therefore has been superseded by madder-lake.

Unfortunately some of the most brilliant colours are perishable to such a degree that they ought never to be used; yet, it seems to me, that just in one branch of art in which of late remarkable progress has been made, I mean landscape painting, the artists, in order to obtain certain effects of colour not easily to be realised, do not always resist the temptation to make use of a number of pigments, the non-durability of which is proved beyond doubt. However that may be, I think it pretty certain that the pigments in themselves play only a subordinate part in the deterioration of oil paintings, and that the principal part belongs to the vehicle with which the colours are ground, and to the liquids which are added during the painting. I hope, therefore, you will excuse my making some elementary explanations about these liquids.

Oil and fat are bodies consisting of carbon, hydrogen, and oxygen. They may be considered as salts in which glycerine, as a basis, is combined with different acids, stearic acid, palmic acid, oleic acid. If oil is exposed to the air it changes; certain kinds of oil remain liquid; others become thicker and darker, and are gradually transformed into hard and opaque bodies. The drying of oils is based upon a chemical process, during which the oil oxidises by absorbing oxygen from the air, and combining a part of it with carbon to form carbonic acid, and another part with hydrogen to form water. The different oils dry with different rapidity, but this rapidity may be modified by the presence of certain substances, or by certain treatment. Linseed oil, for instance, according to the way in which it has been pressed out of the seed, contains more or less mucilaginous substances. These latter impede the drying of the oil, and have therefore to be removed by a refining process. If linseed oil in a shallow vessel is exposed to the air and light, and especially to a green light, it soon begins to dry, and is transformed first into a kind of varnish and gradually into a solid opaque substance. The drying may be quickened by boiling, and more particularly by the addition of lead, zinc, or manganese. In this way a quick-drying oil varnish may be prepared and used as a siccative. It follows that there are certain substances which impede the drying of oils, and others which facilitate it. Amongst the pigments are some which belong to this category of bodies: white-lead, zinc-white, minium, vermilion, for instance, facilitate the drying; others, such as ivory-black, bitumen, madder-lake, will impede it. Supposing, now, we should add to each of the different pigments the same quantity of oil, the drying of it would progress at different rates. But in reality this difference is very greatly increased by the fact that the different pigments require very different quantities of oil, in order to be ground to the consistency requisite for painting.

Pettenkofer quotes the following figures, given to him by one of the colour manufacturers:—

100 p[illegible](weight)	White-lead	... ...	require	12	parts of oil,
,, ,,	Zinc-white	... ...	,,	14	,,

100 parts (weight)	Green chrome ...	require	15	parts of oil.
,, ,,	Chrome-yellow ...	,,	19	,,
,, ,,	Vermilion	,,	25	,,
,, ,,	Light red	,,	31	,,
,, ,,	Madder-lake	,,	62	,,
,, ,,	Yellow ochre	,,	66	,,
,, ,,	Light ochre	,,	75	,,
,, ,,	Cassel's-brown ...	,,	75	,,
,, ,,	Brown manganese	,,	87	,,
,, ,,	Terre verte	,,	100	,,
,, ,,	Parisian-blue	,,	106	,,
,, ,,	Burnt terre verte ...	,,	112	,,
,, ,,	Berlin-blue	,,	112	,,
,, ,,	Ivory-black	,,	112	,,
,, ,,	Cobalt	,,	125	,,
,, ,,	Florentine-brown ...	,,	150	,,
,, ,,	Burnt terra sienna	,,	181	,,
,, ,,	Raw terra sienna ...	,,	240	,,

According to this table a hundred parts of the quick-drying white-lead are ground with twelve parts of oil, and on the other hand, the slow-drying ivory-black requires one hundred and twelve parts of oil.

It is very important that artists should have an exact knowledge of these matters. But it seems to me that they are insufficiently known to most of them. All, of course, know perfectly how different the drying quality of different colours is. But that these different colours introduce into the picture so different a quantity of oil, and how large this quantity is in the colours they buy, and further, that the oil as well as the mediums or siccatives they add to dry the colours, are gradually transformed into a caoutchouc like opaque substance, which envelops and darkens the pigments; and moreover, that the oil undergoes—not in the beginning, but much later on when it is already completely dry—changes of volume, and so impairs the continuity of the picture—all this is not sufficiently known. Otherwise, the custom of painting with the ordinary oil colours to be bought at any colourman's, would not have been going on for nearly a hundred years in spite of all the clearly shown evil results; results due, chiefly, TO THE PRINCIPAL ENEMY OF OIL PAINTING, THAT IS TO SAY, THE OIL.

That the masters of the fifteenth and sixteenth centuries did not use colours prepared in this way you may consider as absolutely certain; and if we hear the lost secret spoken of, and if we read that the pupils of the old masters had to pledge themselves to keep the secret, we may be sure that it is neither the method of painting nor the pigment used for it which is concerned in that secret, but exclusively the way of preparing the colours. The preparation was a very complicated one, varying with the different pigments; and we know that the pupils passed six years, that is half of the apprenticeship, in grinding the colours for the master.

And therefore it is to this very point that everyone who wishes to study the method of the old masters must first of all direct his attention. I, too, was led by the study of this question to analyse and restore old pictures. The possibility of making such analysis we owe to the relation between the old masters and their pupils. Of course we could not dissect or chemically analyse works of Titian or Raphael. But fortunately the pupils painted with the same material and by the same method as the masters, and thousands of pictures by the pupils, *well preserved* or in different stages of decay, may be easily procured.

I have myself, from among a very great number of such pictures, selected about one hundred specimens, part of which I have brought before you. As their artistic value is not, as you perceive, of the highest description, we need not feel any scruple in experimenting upon or even destroying them, if we can thereby gain any valuable information.

(*To be continued.*)

GAS-LIGHTING BY ELECTRICITY

FOR some time past the street lamps in Pall Mall, Waterloo Place, and part of Regent Street, have been connected by wires, which may have led the uninitiated to think that a new method of fixing telegraphic wires was about to be adopted. This is not the case, however, for although the wires were connected with a battery, they were not intended to convey telegraphic message, but to experiment on a new method of lighting street lamps by means of electricity. The inventor of this method is Mr. St. George Lane Fox, who recently described his invention to the Society of Arts. Should Mr. Fox's method be adopted, the wires, instead of running from lamp to lamp above ground, will be carried along under ground, and the only thing visible would be a small piece of boxed-in mechanism just under the burner of each lamp. The experiment which was made on Saturday afternoon was not, we believe, completely successful. The magneto-electric machine and the battery which supply the current were placed in a small temporary instrument-house at the bottom of Waterloo Place. At the first trial the whole of the lamps in the circuit were lighted by the current, though in a second trial some of the lamps failed to respond to the current; but that this was owing to some local cause is probable from the fact that the first and last lamps in the circuit always responded to the discharge. We shall endeavour to explain the method adopted by Mr. Fox.

Fig. 1.

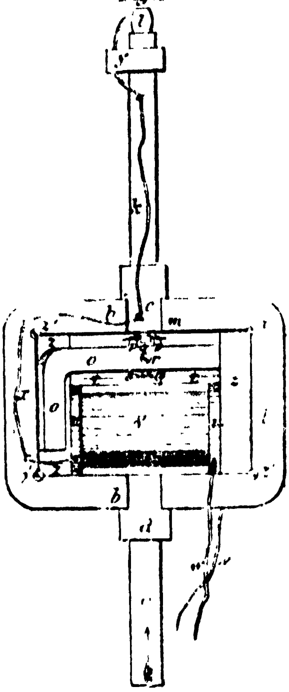

Fig. 2.

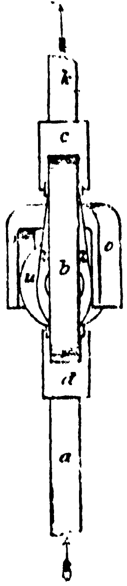

In the first place he supplies every lamp with an apparatus similar to Fig. 1; next the lamps must be connected with an insulated conductor, so that, starting from a central station, a wire would travel through each of these machines and back again to the station. Mr. Fox proposes that several of these circuits, each connecting and controlling 200 or 300 lamps, should proceed or radiate from a central station, so that from one point several thousand lamps could be operated upon almost instantaneously.

The method by which he has succeeded in producing the ignition of the gas at a considerable distance, and at numerous points, is by supplying each lamp with a small induction coil, so that the primary wires of each one of these induction coils forms part of the circuit, so in fact as to preserve without a break the metallic continuity of the line. After several experiments it occurred to him that in reality the amount of work to be done in producing a number of small electric sparks was extremely minute, although at the same time requiring to be produced almost instantaneously. Now the amount of work which an electric battery will produce is dependent on the time during which action continues, and in a single instant, or say the thousandth part of a second, the actual amount of power available is naturally extremely small, and he thought that if he could by any means accumulate this power for a short time and then bring it suddenly to bear upon the circuit, the desired result would be obtained. By means of an apparatus he succeeded in accumulating the electric current and storing it up into the condenser or electric reservoir, which is composed of glass plates and tin-foil laid side by side alternately.

The condenser, however, is not charged direct by the battery, but the current is made to work this Ruhmkorff induction coil, from which there is derived a current having an enormously increased electromotive force, and it is this electricity that is stored up in the condenser.

Having charged the condenser in this fashion, the whole of the electricity is at once sent through the line, and produces most extraordinary results. So much, then, for the lighting of the gas. The process of turning on and off the gas, although involving many important details, is very simple. Mr. Fox makes use of the soft iron core which runs through the centre of the coil to produce a reciprocating horizontal motion of a permanent horse-shoe magnet, suspended on needle-points just above the coil. The soft iron core with the primary coil is, in fact, an electro-magnet, which can be magnetised so as to render its poles reversible at pleasure; the magnets are carried in a small metal frame, having a passage through it for the gas to pass to the burner at the top, and being provided with a stop-cock, or valve, which is actuated by the reciprocating magnet. The whole of this apparatus is inclosed in an air-tight metallic case, which measures about 2¼ inches high, by 2½ wide, and is screwed on to the supply-pipe in the lamp, the insulated conductor or line-wire being carried down the interior of the lamp-post and laid under ground, except, of course, where an overhead line is admissible. The turning of the gas on and off is accomplished by opening and closing what may be termed an electric needle-tap. The plug of this needle-tap is cylindrical, and about a quarter of an inch in diameter, and is carried in a socket, which it fits rather loosely. It is made to turn in this socket by the action of the reciprocating magnet, a couple of studs, which are brought into contact with a small pin or lever connected with the plug, and forming, in fact, the handle of the stop-cock. The annular space between the plug and the socket (which is about one-thousandth part of an inch) is filled with some liquid, which is retained by capillary attraction between the two surfaces, the joint being thus rendered perfectly gas-tight. The oil of bitter almonds or glycerine are both well adapted for this purpose, on account of their non-oxidisable character, and from the power they possess of resisting the action of very low temperatures. A special feature in the apparatus is the introduction of a fixed core, which can be magnetised, so as to render its poles reversible at pleasure, and in conjunction with it a movable magnet, the polarity of which is permanent. An electric current sent either forwards or backwards for a few seconds will turn the gas on or off in every lamp in the circuit according to the direction of the current.

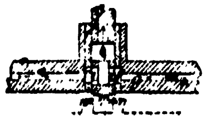

Fig. 4.

Fig. 6.

Fig. 7.

Fig. 8.

Fig. 9.

To put the system into practical operation, there would be for any district of, say two or three thousand lamps, a central station, from which the wires would proceed in every direction, so as to command a number of distinct circuits; all that is necessary to have at the central station would be a battery of some sort. Mr. Fox would much prefer a magneto-inductor. By means of a switch and a commutator the electric current from this machine can be directed so as to operate separately on each one of the circuits, and by this means turn the gas on or off. When the gas is turned on it is lighted by sending a discharge from the condenser. It is constructed of alternate metallic plates, with an insulator or dielectric between them; the conducting surfaces in this case are of tinfoil, and the dielectric of crown glass. The coil used for charging the condenser need not give more than about three-quarters of an inch spark in the air. The discharge, like the current, will of course have to be sent through each circuit separately, and this is also done by means of the switch arrangement.

The accompanying figures will enable the reader more clearly to understand the description we have given above.

Fig. 1 is a front elevation, Fig. 2 a side elevation, and Fig. 3 a plan of the apparatus; Fig. 4 is a plan of the permanent magnet; Figs. 5 to 9 represent details to be referred to.

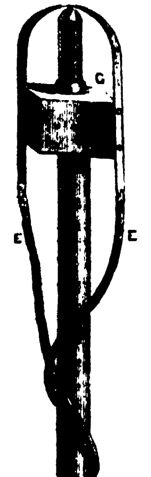

Fig. 10.

a is the gas-pipe leading from any ordinary source of supply; *b b* is a rectangular frame of white metal or brass, cast or made with a hollow core, and having two cylindrical portions, *c d*. The part *d* is screwed upon the gas-pipe *a*, which supports the apparatus, and the part *c* receives the stop-cock; this cock, which is shown in sectional elevation in Fig. 5, and in sectional plan in Fig. 6, is composed of a brass tube *e* (shown separately in Fig. 7), which fits into the cylindrical part *c*, and has two openings, *f f*, corresponding with the passages *g g*, in the opposite sides of the frame *b b*; *h* is the plug of the cock (shown separately in Fig. 8); it is made with a very slight downward taper [illegible] has two apertures or ways *i i*, corresponding with the openings *f f* in the tube *e*, and it is hollowed out in the middle. When the gas is turned on, the apertures *i i* come opposite the openings *f f*, the gas having then a free passage from the pipe *a* through the two sides of the frame *b b*, and into and through the plug *h*. It will be seen on reference to Fig. 6, that a small turn of the plug is sufficient to open or close the cock. *k* is a pipe screwed into the tube *e*, and leading to the burner *l*. *m* is a projection at the lower end of the plug, and *n* is a pin passed through the same. The plug is supported on the point of the pivot on which a magnet turns, so that very little power is required to turn the plug. *o* is a permanent magnet, which may be either cast in steel, with the two projecting pieces *p p*, or made out of a steel bar bent into the proper shape, and in this case the projections *p p* are produced by screwing in two pieces of metal. *q* is the pivot on which this magnet turns; it is passed through a vertical hole in the magnet, and fixed by a screw *r*. The lower end of the pivot rests in a steel step *s*, which is supported by a small wooden beam *t*, secured to the ends of the wooden bobbin *u*. *v* is the induction-coil; it is composed of a core of soft iron wires, two layers of primary wires wound with covered copper wire of about No. 20 BWG, and upon these about ten to fifteen layers of secondary wire of about No. 40 BWG. The primary wires *w w* form part of the circuit by which the lamps to be lighted or extinguished simultaneously are connected. One end of the secondary coil is connected to an insulated wire *x*, leading to the burner *l*, where it terminates in a platinum point, and the other end is connected to the frame *b*, or to any other metallic part of the apparatus, so as to be in metallic connection with the burner. The insulated wire *x* passes through an earthenware support *y* (seen in plan in Fig. 9), fixed to the pipe *k*. The soft iron core projects about three-eighths of an inch from each end of the wooden bobbin *u*. The bobbin is fastened to wooden supports which are fixed to the frame *b* by screws *z¹ z¹*.

Fig. 10 (for the use of which we are indebted to the Society of Arts) is a view of the complete apparatus as attached to a gas lamp.

AMERICAN SCIENCE

THE March number of the *American Journal of Science* opens with a valuable paper, in which Prof. Norton collates the various observations made on Coggia's comet. The theory of cometary phenomena he arrives at is (briefly) that the direct action of the sun on the side of the nucleus exposed to the solar rays is to form an envelope of gaseous carbonic oxide. This envelope of diamagnetic gas is traversed by the ideal lines of magnetic force proceeding from the nucleus, which are also lines of conduction through the gas. The electricity set free by the ascending currents of gas, by reason of the diminished gaseous pressure, is propagated along these lines, and the impulsive force of the electric currents detaches streams of the successive molecules of the gas in the direction of the lines of conduction. Both the nucleus and the sun exert repulsive forces on the escaping molecules; but their effective actions may be either repulsive or attractive, according as their attraction prevails over the attraction of gravitation, or the reverse. The author elucidates this theory at some length.

In a reply to Mr. Mallet's review (in the *Philosophical Magazine*) of General Abbott's paper on the velocity of transmission of earth-waves, in which the value and accuracy of the Hallet's Point observations were doubted, the General describes some new observations on the subject, which seem to establish these points: 1. A high magnifying power of telescope is essential in seismometric observations. 2. The more violent the initial shock the higher is the velocity of transmission. 3. This velocity diminishes as the general wave advances. 4. The movements of the earth's crust are complex, consisting of many short waves first increasing and then decreasing in amplitude, and, with a detonating explosive, the interval between the first wave and the maximum wave, at any station, is shorter than with a slow-burning explosive.

A new method for decomposition of chromic iron, proposed by Mr. Smith, consists in exposing it (in an exceedingly fine state) with bromine to a temperature of 180° C. from two to three days. Prof. Marsh furnishes an account of some new Dinosaurian reptiles.—Prof. Kimball describes some experiments on journal friction at low speeds.—There are also notes on some reactions of silver chloride and bromide, brightness of the satellites of Uranus, &c.

The new number of *Appalachia*, the journal of the Appalachian Mountain Club, contains a valuable address by the president, Dr. S. H. Scudder, in which he reviews the principal scientific expeditions in the United States during the past year. Dr. Scudder himself is attached to the Hayden Survey, and made the discovery of the beds of fossil insects at Florissant, near Manitou, Colorado. During the past year 20,000 fossil insects have been exhumed from this quarry.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The fifth and final report of the Syndicate appointed in May, 1875, to consider the requirements of the University in different departments of study, has been issued. The Syndicate have considered the question of the residence to be required of professors. They are of opinion that it is desirable (1) that the time for which the University may require the residence of professors shall be left to be determined by the University in the case of each professorship, without any general statutable restriction: (2) that no professor shall be considered to satisfy the condition of residence who is not for the time required making his home within a mile and a half of Great St. Mary's Church, unless special permission, available for not more than one year at a time, but renewable, be granted by the Vice Chancellor and Sex Viri, and that such permission shall not be granted unless the Vice Chancellor and Sex Viri are satisfied that the professor has made such arrangements as will secure his being reasonably accessible in Cambridge during term time. The Syndicate have also had under their consideration the importance of individual personal intercourse between students and teachers, and it has also been suggested that the inspection and revision of students' note-books by the teacher may in many cases be of considerable use. The precise manner in which such personal intercourse may be most effectually secured will probably vary very much in different subjects and for different teachers, but it seems important that the arrangements should be such that the professor himself may in all cases see a portion of the work of his class, so as to make himself accurately acquainted with their wants. The Syndicate have referred to the Board of Medical Studies the question whether it is desirable to found a complete medical school in Cambridge so as to make it possible for a student to complete his whole medical course here, or whether it is better for all concerned, while making the teaching at Cambridge as perfect as possible in the scientific subjects which are the basis of medicine, to leave students to carry on elsewhere the greater part of their clinical studies and most of what relates directly to the practice of medicine. The reply of the Board of Medical Studies states that they consider it inexpedient that students should complete their whole professional education at any single medical school, and that it is therefore desirable that students should pursue their studies away from Cambridge for a year or more before commencing practice, either before or after their final M.B. examination. They believe, however, that it would be in most cases advantageous to students to carry their medical studies in Cambridge further than is usually done at present, and in some cases as far as the final M.B. examination, and they are therefore of opinion that the University should provide systematic instruction in all the subjects necessary for a medical degree, as is done at other Universities. In order that this may be carried out satisfactorily the Board of Medical Studies think that the University should provide:—1. A Professor of Pathology. 2. A Professor of Surgery. 3. Systematic teaching in (1) midwifery and the diseases peculiar to women (2) medical jurisprudence; (3) sanitary science; (4) mental diseases. 4. Systematic clinical teaching.

R.G.S. PUBLIC SCHOOLS' PRIZE MEDALS.—The following is the award of the Public Schools' Prize Medals annually given by the Royal Geographical Society:—Physical Geography—Gold Medallist, William John Newton, of Liverpool College; Silver Medallist, Christopher Mounsey Wilson, of Clifton College; Honourably Mentioned—E. G. Harmer, University College School; M. H. Clifford and M. A. Soppitt, of Dulwich College; and J. S. G. Pemberton, of Eton College. Political Geography—Gold Medallist, William Wallis Ord, of Dulwich College; Silver Medallist, George Arnold Tomkinson, of Haileybury College; Honourably Mentioned—A. R. Ropes, of the City of London School; A. Kay, of Rossall School; and D. Howie, of Dulwich College.

GREIFSWALD.—The University has received a grant of 381,000 marks for a new library building, and 200,000 marks for the construction of a physical laboratory.

SCIENTIFIC SERIALS

Bulletin of the Nuttall Ornithological Club. A Quarterly Journal of Ornithology. Vol. III. January, No. 1.—This journal, on entering upon its third volume, has increased its quarterly numbers from a thin part of twenty-four pages to a part containing forty-eight pages and a coloured plate. It will continue, as before, under the editorial management of Mr. J. A. Allen, assisted by Prof. Baird and Dr. E. Coues, and it is intended that the volume for the current year should contain an exhaustive *résumé* of the current literature relating to North American Ornithology. The present number contains—Dr. E. Coues: On *Passerculus bairdi* (with plate), and *P. princeps.*—H. W. Henshaw on the species of Passerella.—W. A. Cooper: On the breeding of *Carpodacus purpureus*, var. *Californicus.*—W. Brewster: On the first plumage of North American birds.—J. A. Allen: On Wallace's theory of birds' nests.—N. S. Goss: Breeding of the duck hawk in trees.—Notes of recent literature and general notes.

Reale Istituto Lombardo di Scienze e Lettere, Rendiconti, vol. xi. fasc. iii.—On the action of so-called catalytic force viewed according to the thermodynamic theory, by M. Tommasi.—Study on the dominant diseases of vines, by M. Garovalio and Cattaneo.—On the chronology of Tyrrhenian volcanoes, and on the hydrography of the Val di Chiana previously to the miocene epoch, by M. Verri.—On the permanent magnetism of steel at different temperatures, by M. Poloni.—On the plasmogonic production of leptothrix and leptomitus, by M. Cattaneo.—On the refrigeration of pulverulent metallic solids (continued), by M. Cantoni.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, February 28.—"On the Reversal of the Lines of Metallic Vapours," by G. D. Liveing, M.A., Professor of Chemistry, and J. Dewar, M.A., F.R.S., Jacksonian Professor, University of Cambridge. No. 1.

In order to examine the reversal of the spectra of metallic vapours, the authors observe the absorptive effect produced on the continuous spectrum emitted by the sides and end of the tube in which the volatilisation takes place. For this purpose they use iron tubes about half an inch in internal diameter, and about twenty-seven inches long, closed at one end, thoroughly cleaned inside, and coated on the outside with borax, or with a mixture of plumbago and fireclay. These tubes are inserted in a nearly vertical position in a furnace fed with Welsh coal, which will heat about ten inches of the tube to about a welding heat, and they observe through the upper open end of the tube, either with or without, a cover of glass or mica. To exclude oxygen, and avoid as much as possible variations of temperature, they introduce hydrogen in a gentle stream through a narrow tube into the upper part only of the iron tube, so that the hydrogen floats on the surface of the metallic vapour without producing convection currents in it. By varying the length of the small tube conveying the hydrogen, they are able to determine the height in the tube to which the metallic vapour reaches, and to prevent further displacement of the vapour, and thus to maintain different lengths of the iron tube full of metallic vapour at a comparatively constant temperature for considerable periods of time.

By this means the following observations have been made up to the present time:—

The first metal experimented on was thallium, one of the most volatile of metals. After arranging the current of hydrogen so as to keep the tube free from air, but without any rapid movement of the gas, they saw the characteristic line reversed, and maintained it so for a considerable time.

The metal indium, closely allied in its behaviour and volatility to thallium, was next examined, and they observed the bright blue line reversed. This was most plainly visible when that portion of the vapour which was nearest to the sides of the tube was looked through.

They had great difficulty in preventing the oxidation of magnesium in the tube, and in using tubes wider than half an inch, did not succeed in getting any reversal, but with half-inch tubes the *b* lines were clearly and sharply reversed, also some dark lines, not measured, seen in the blue. The sharpness of these lines depended on the regulation of the hydrogen current, by which the upper stratum of vapour was cooled.

A piece of metallic lithium was introduced, and gave no results. Sodium was next added in the same tube, and this did not bring out the reversal of the lithium lines. Similarly, chloride of lithium and metallic sodium, introduced together, gave no better results. To a tube containing potassium vapour, some lithium chloride was added, but no lithium line appeared. On adding metallic sodium to this atmosphere, and more lithium chloride, the bright-red lithium line appeared sharply reversed, and remained well defined for a long time. It is worthy of observation that the lithium line was only reversed in a mixture of the vapours of potassium and sodium, and it seems highly probable that a very slightly volatile vapour may be diffused in an atmosphere of a more volatile metal, so as to secure a sufficient depth of vapour to produce a sensible absorption. This would be analogous to well-known actions which take place in the attempt to separate organic bodies of very different boiling points by distillation, where a substance of high boiling-point is always carried over, in considerable quantity, with the vapour of a body boiling at a much lower temperature. It is a matter for future investigation how far chemical interactions taking place in a mixture of metallic vapours affect the volatility of a third body, and what relation, if any, this may have to such phenomena as the increased fusibility of mixtures of salts of potassium and sodium, and the well-known fluidity of the alloy of those metals.

As the authors have had occasion to use sodium and potassium in their tubes, they have had opportunities of observing the absorption spectra of these metals, and they find that there is a great deal yet to be observed in regard to these spectra. Up to the present time they have not observed any of the appearances noted by Lockyer, "On a New Class of Absorption Phenomena," in the *Proceedings* of the Royal Society, vol. xxii., but they have repeatedly noted the channelled-space spectrum of sodium described by Roscoe and Schuster, in the same volume of the *Proceedings*. They observed in their tubes no channelled space absorption by potassium, but continuous absorption in the red and one narrow absorption band, with a wave-length of 5,730, not corresponding with any bright line of that metal.

With reference to the absorption spectrum of sodium vapour they remark that it is by no means so simple as has been generally represented. The fact that the vapour of sodium in a flame shows only the reversal of the D lines, while the vapour, volatilised in tubes, shows a channelled space absorption, corresponding to no known emission spectrum, appears to be part of a gradational variation of the absorption spectrum, which may be induced with perfect regularity. Experiments with sodium, carried out in the way described, exhibit the following succession of appearances, as the amount of vapour is gradually diminished, commencing from the appearance when the tube is full of the vapour of sodium, part of it condensing in the cooler portion of the tube, and some being carried out by the slow current of hydrogen. During this stage, although the lower part of the tube is at a white heat, we have always noticed, as long as the cool current of hydrogen displaced metallic vapour, that, on looking down the tube, it appeared perfectly dark. The first appearance of luminosity is of a purple tint, and, with the spectroscope, appears as a faint blue band, commencing with a wave-length of about 4,500, and fading away into the violet. Next appears a narrow band in the green, with a maximum of light, with a wave-length of about 5,420, diminishing in brightness so rapidly on either side as to appear like a bright line. This green band gradually widens, and is then seen to be divided by a dark band, with a wave-length of about 5,510. Red light next appears, and between the red and green light is an enormous extension of the D absorption lines, while a still broader dark space intervenes between the green and the blue light. The dark line in the green (wave-length about 5,510) now becomes more sharply defined. This line appears to have been observed by Roscoe and Schuster, and regarded by them as coinciding with the double sodium line next in strength to the D lines, but it is considerably more refrangible than that double line. In the next stage, the channelled space spectrum comes out in the dark space between the green and blue, and, finally, in the red. Gradually the light extends, the channels disappear, the D lines absorption narrows, but still the dark line in the green is plainly discernible. Lastly, there is only D lines absorption. The blue and the streak of green light at first observed seem to the authors due to luminosity of the vapour itself, where it is somewhat cooled, the later stages being mixed phenomena of absorption and emission.

As the absorption line, with wave-length about 5,510, has not been distinctly recorded by other observers, they have endeavoured to trace it under somewhat different conditions from that of the vapour volatilised in white hot-iron tubes. This absorption-line is easily seen when a gas-flame is observed through a horizontal glass tube, about three inches long, containing sodium volatilised in the middle of the tube by the heat of a Bunsen's burner, and equally well whether the tube contains hydrogen or nitrogen, besides sodium. They have also observed the same absorption-line when a piece of commercial magnesium ribbon (which always contains sodium) is ignited in a horizontal position, so that the metal melts and produces an elongated flame. It is of some interest to note that absorption-lines of about this wave-length, in the solar spectrum, are given by Kirchhoff and Angstrom not corresponding with emission lines of known elementary bodies.

When potassium vapour is observed, whether in the iron tube or in a glass tube, an absorption-line is seen, with a wave-length of about 5,730, which is more refrangible than the yellow double emission line of potassium, and does not correspond to any known bright line of that metal.

They reserve, for a future communication, the discussion of the identity or non-identity of these absorption-lines with lines in the solar spectrum and the inferences which may be drawn from such determination.

The method of observation described may be used to observe emission-spectra as well as absorption-spectra, for if the closed end of the tube be placed against the bars of the furnace so as to be relatively cooler than the middle of the tube, the light emitted by the vapours in the hottest part is more intense than that emitted by the bottom of the tube. This succeeds admirably with sodium, but they have not specially observed it with other vapours.

Chemical Society, March 22.—Dr. Gladstone, president, in the chair.—The following papers were read:—On aromatic nitrosamines, by Dr. O. N. Witt. The author gives an account of his study of some complicated reactions of diphenylnitrosamine. He has found that ordinary ethylic nitrite contains nitric acid, and has therefore used mixtures of pure amylic nitrite and nitric acid for acting on diphenylamine, and has obtained mononitrodiphenylnitrosamine in light yellow plates melting at 133·5° C., and two bodies which, on the removal of their nitroso groups, yielded dinitrodiphenyamine and an isomeric substance. The final product of the action of strong nitric acid is hexanitrodiphenylamine.—The next paper was on a new process for the volumetric estimation of cyanides, by J. B. Hannay. The cyanide is dissolved in water, and the solution rendered alkaline by ammonia. A standard solution of mercuric chloride is run in with constant stirring until the liquid is distinctly opalescent. The end reaction is sharply marked and very delicate. The presence of silver does not interfere, so that the process can be used for estimating the cyanides present in a plating bath.—The last paper was on certain bismuth compounds, Part 7, by M. M. P. Muir. The author has compared the behaviour of bismuthous and phosphorous chlorides in certain reactions; the latter substance acts as a reducing agent in some cases in which the former does not exert any such action. The author has also studied two oxalates of bismuth, the production of the so-called bismuthates, and some experiments with bismuthous iodide.—Mr. Williams exhibited a fine sample 24 oz. of natural salicylic acid, also about one gallon of pure methylic alcohol.

Linnean Society, March 21.—W. Carruthers, F.R.S., vice-president, in the chair.—Mr. G. T. Saul exhibited an example of the enormous development of adventitious roots from a species of *Berberis*.—On behalf of Mr. J. Willis Clark of Cambridge, there was exhibited mounted specimens of the male, female, and young of the fur-bearing seal of the North Pacific. Mention was made of the "rookeries" of these creatures, containing over 3,000,000 seals in a compact area. Like old Turks, a male dominates over a harem of a dozen or fifteen females, which he guards with jealous care, for two months or more, never stirring from the spot, and meantime fights terrific battles for its maintenance. A neutral zone exists to the rear of the breeding-grounds, where the enforced bachelors and adolescent young of both sexes repair. These come and go continuously, passing to and fro through free lanes of passage. Others of these animals delight in dashing among the breakers on the surf, or in droves frolic and play on the sand and grassy dunes adjoining the more rocky ground of the "rookery." The method of shaving the fleshy side of the skin, thus cutting loose the roots of the long coarse hairs, and retaining the superficial fine fur of commerce was explained, as also other interesting points in the economy and natural history of the Otaries.—The Secretary read the gist of a paper on the venation of the leaf of hemlock (*Conium maculatum*), by Mr. J. Gorham. The latter's observations show that in a piece ¼ inch long, by ⅛ inch wide, by registration of the veinlets in a tabular form, and constructing these in figure, an exact counterpart of the venation of the entire leaf results. Comparisons of leaves of different umbelliferous genera prove that each can be detected and recognised from the merest fragment.—A communication was made by Mr. B. Clarke on a new arrangement of the classes of zoology, founded on the position of the oviducts, or when these are absent on the position of the ovaries, including a new mode of arranging the mammalia.—A notice in abstract was given on some genera of the Olacaceæ, by Mr. J. Miers. He describes a new genus, Rhaptarrhena, from Brazil, allied to Aptandra; also three other genera, Myoschilos, Arjona, and Quinchamalium, which possess a distinct though small calyx and separate calycle.—The Rev. M. J. Berkeley and Mr. C. E. Broome gave a list of fungi from Brisbane, Queensland. Among these Agarics, Clavarei, and fleshy fungi are scarce; interesting forms of Polyporei obtain while leaf-parasites are poorly represented. Some species are identical with Ceylon and South American kinds, and several are common to Europe.—The following gentlemen were elected Fellows of the Society:—John Evans, F.R.S., C. P. Ogilvie, Arthur Veitch, and Sydney H. Vines, B.A.

Zoological Society, March 10.—Mr. Arthur Grote, vice-president, in the chair.—The Secretary exhibited the type specimen of *Dicrurus marginatus* of Blyth, and pointed out its identity with *Muscipipra vetula* (fam. Tyrannidæ).—Mr. J. W. Clark, F.Z.S., exhibited and made remarks on some stuffed specimens of the Sea Lion (*Otaria ursina*) of the Prybylov Islands, which had been presented to the Museum of the University of Cambridge by the Alaska Commercial Company.—A communication was read from the Marquis of Tweeddale, F.R.S., containing the sixth of his contributions to the ornithology of the Philippines. The present memoir gave an account of the collections made by Mr. A. H. Everett in the Island of Leyte.—Mr. P. L. Sclater, F.R.S., read a report on the collection of birds made during the voyage of H.M.S. *Challenger*, in the Sandwich Islands, and pointed out the characters of a new species of duck, of which it contained specimens, and which he proposed to call *Anas wyvilliana*.—A communication was read from Mr. W. A. Forbes, F.Z.S., containing notes on a small collection of birds from the Samoan Islands and the Island of Rotumah, Central Pacific.—A communication was read from Mr. F. Nicholson, F.Z.S., containing a list of the birds collected by Mr. E. C. Buxton, at Darra Salam, on the Coast of Zanzibar.—Messrs. F. Du Cane Godman and Osbert Salvin gave descriptions of new species of Central American butterflies of the family Erycinidæ.—Prof. A. H. Garrod, F.R.S., read some notes on the visceral anatomy of *Lycaon pictus* and *Nyctereutes procyonides*.—A communication was read from Mr. Andrew Anderson, F.Z.S., containing the description of a new Indian *Prinia*, obtained in the Bage-ur Valley, North-Western Himalayahs, which he proposed to name *Prinia poliocephala*.

Meteorological Society, March 20.—Mr. C. Greaves, president, in the chair.—Mr. B. L. Smith was elected a Fellow.—The discussion on Dr. Tripe's paper on the winter climate of some English sea-side health resorts was resumed and concluded, after which the following papers were read:—Notes on a waterspout, by Capt. W. Watson, F.M.S.—Notes on the occurrence of globular lightning and of waterspouts in Co. Donegal, Ireland, by M. Fitzgerald.—Observations of rainfall at sea, by W. T. Black.—The discussion on the subject of waterspouts and globular lightning was adjourned till the next meeting, on April 17.

Anthropological Institute, March 26.—Mr. John Evans, D.C.L., F.R.S., president, in the chair.—The following new members were announced:—Dr. Sebastian Evans and Dr. Allen Thomson, F.R.S.—A paper was read by Mr. Francis A. Allen on the original range of the Papuan race. This paper was a brief *résumé* of the opinions held by many anthropologists with regard to the origin, characteristics, and distribution of these races, and an attempt to prove that they once extended on the west as far as Africa, and on the east as far as America. The writer especially dwelt upon the statements of Herodotus with regard to the eastern and western Ethiopians, and the black Colchians, and referred to the legend of the Asiatic Memnon, and the existence of black races in Central America, within the historic period. The director then read a paper by Dr. Julius von Haast, F.R.S., on some ancient rock paintings in New Zealand. The author considered that when these rock paintings were carefully studied by archæologists and linguists, they would prove that at one time there had been an introduction of a far higher civilisation than the Maories ever reached.

Institution of Civil Engineers, April 2.—Mr. Bateman, president, in the chair. The paper read was on the Huelva Pier of the Rio Tinto Railway, by Mr. T. Gibson, Assoc. Inst. C.E.

EDINBURGH

University Chemical Society, February 20.—John Gibson, Ph.D., F.R.S.E., presiding.—Mr. W. L. Goodwin read a paper on a method of removal of iron from cupric sulphate for analytical purposes, in which he stated that this could be performed by the replacement of the iron by cupric hydrate.—Mr. Alexander Macfarlane, M.A., B.Sc., read a paper on the disruptive discharge of electricity, in which he gave the difference of potential necessary to produce sparks at different distances up to ten millimetres, and also with different pressures and gases as dielectrics.

February 27.—W. Inglis Clarke, B.Sc., in the chair.—A paper on electrolysis was read by R. M. Morrison, D.Sc., Chemical Demonstrator of the University, in which he traced the history of electrolysis down to the present time, showing that as recently as 1840 the art was practically in its infancy, and that at the present day it was in numberless ways made use of. The chief points of theoretical and practical interest were dwelt upon, both with regard to the various metals which could practically be used, and to the solvents from which the best results were obtainable.

Wassmuth.—Contribution to study of electricity, magnetism, terrestrial currents, magnetic variation, declination, inclination, and intensity, by M. Daubrawa.—On a simple method of drawing a tangent to the ellipse and parabola, by M. Zimels.

PARIS

Academy of Sciences, April 8.—M. Fizeau in the chair.—The following among other papers were read:—Extract from a work by M. Chevreul, on the vision of colours. M. Chevreul describes some effects obtained by rotation, with diminishing speed, of a disc having one half red the other white, as compared with a similar disc viewed when at rest.—On the transparence of coloured flames, by M. Gouy. For measuring very weak radiations the objective of the collimator of a spectroscope is half covered with a plane mirror which reflects the rays from a second collimator parallel to the axis of the first. Thus in the focal plane of the telescope are got two superposed spectra, received on a slit parallel to the lines, which serves as eye-pieces. The two flames compared send their rays through the two collimators respectively; the eye sees through the prisms half of each of the objectives as a circle with its two halves of the same colour, but differing in brightness. The same brightness is given them by means of two Nicols on the second collimator. The angle of the principal sections is then read, and indicates the result of experiment. Coloured flames, got from a mixture of common gas and air with a finely-powdered salt in it, were carefully regulated and inclosed in another flame at the same temperature, but without metallic vapour. M. Gouy demonstrates the transparency of flame for the rays it does not emit, and for its own radiations.—On the variation of indices of refraction in mixtures of isomorphous salts, by M. Dufet. He finds that the differences between the indices of a mixture of two isomorphous salts and those of the component salts are in inverse ratio of the number of equivalents of the salts present in the mixture.—Direct fixation of oxygen and sulphur in benzine and toluene, by MM. Friedel and Crafts. Such fixation is accomplished by the intervention of chloride of aluminium; the authors cite it as supporting their hypothesis about this class of reactions.—Researches on nitrification by organic ferments, by MM. Schlœsing and Muntz. The vegetable organisms, mould and mycoderms, which are strongly productive of combustion of organic matter, do not produce nitrification; on the contrary, they transform nitric acid, placed at their disposal, first into organic matter then, partly, at least, into free nitrogen, the last phenomenon being often attended by production of ammonia. Hence they effect a loss of the combined nitrogen on the surface of the globe. The function of nitrifying combined nitrogen seems to be the special attribute of a group of particular beings, and not common to all the organisms which are intermediaries of combustion.—Absorption by the living organism of carbonic oxide introduced in small quantities into the atmosphere, by M. Gréhant. Man or an inferior animal caused to respire for half an hour in an atmosphere containing only $\frac{1}{770}$ of carbonic oxide, absorbs this gas sufficiently for about half of the red corpuscles combined with the gas to become incapable of absorbing oxygen, while in an atmosphere containing $\frac{1}{1470}$ of carbonic oxide, about a fourth of the red corpuscles are combined with this gas.—On the organ called chorda dorsalis in *Amphioxus lanceolatus*, by MM. Renaut and Duchamp. Amphioxus deprived of red blood containing hæmoglobin in its special elements, has no longer a chorda dorsalis comparable in its structure to that of all vertebrates.

THE COMING TOTAL SOLAR ECLIPSE[1]

II.

IN my former article I referred to the possible employment of slitless spectroscopes during the coming eclipse, the prism being replaced by a grating in some cases. It will be convenient here to give the results arrived at by the Siam Expedition with an instrument of this description, which, for shortness, was called a prismatic camera.

The plates secured present at first sight a very puzzling appearance; they are unlike anything ever obtained before, and a good deal of thought had to be spent upon them before all the knowledge they were afterwards found capable of furnishing to us was properly appreciated. One of the plates was exposed for one minute at the commencement of totality, the other for two minutes at the end. The differences between them are those due to the phases of the eclipse. In the first, two strong protuberances close together are photographed; these are partially covered up in the second, while another series is revealed on the following limb in consequence of the motion of the moon over the sun.

Now in both the photographs—that exposed for one minute and that exposed for two—the strongest of the prominences are repeated three times, that is to say, three spectral images of them are visible, each of these images being produced by light of different wave-lengths which the prominences emitted.

The question is what are these particular wave-lengths thus rendered visible? Unfortunately no photograph was taken of the cusps either before or after totality; a scale therefore was out of the question; and when the task of assigning wave-lengths to these spectral images fell upon Dr. Schuster and myself, while we were preparing the Report which was sent in to the Royal Society last year, the difficulties we encountered were very considerable.

Everybody I think will consider that we were justified in expecting the lines of hydrogen to be represented in such a photograph. Now the photographic hydrogen lines are those at F, near G and at *h*, and the silver salts usually employed are such that the action is most intense near G, less intense near *h*, and least at F; the running down from G to F being rapid, and that from G to *h* much more gradual, so that while at one end F may be said to be the limit of photographic activity, at the other it is continued long past *h*. We were therefore justified in assuming as the preliminary hypothesis, that the image of least refrangibility was produced by the F light of hydrogen, the more so as the continuous spectrum also photographed—which continuous spectrum, as we had independent means of determining, came from the base of the corona—gave us also an idea of the part of the spectrum in which each image was located.

Taking then F as a starting point and assuming the next line to be the one near G, we had a quite satisfactory method of checking the assumption, by comparing the real distance between the images with the calculated one.

A goniometer was therefore brought into requisition, and the angular distance between F and the line near G carefully measured in order to determine the dispersion of the prism actually employed. This dispersion was one which should bring the images about as far apart as they were actually found to be; this therefore was so far in favour of our assumption, that is to say, it did look as if we had got hold, on the photographs, of images of the prominences built up by the F and G light of hydrogen.

It was next the turn of the third line, the one at *h*. On the assumption already made, it was easy to determine the distance from the G image, at which the one representing *h* should lie. In this place, however, we found no image whatever of any of the prominences.

Now this was a very extraordinary result, and there was only one way, so far as we could then see, of accounting for it. Dr. Frankland and myself, nearly ten years ago now, produced evidence which seemed to indicate that this line of hydrogen was only produced by a very high temperature. This being so, then, we should have to conclude that the prominences were of a relatively low temperature; this, however, I am far from saying, and here there is undoubted work of the greatest value to be done at the next eclipse, and I for one feel certain that our American cousins will do it.

I have not, however, yet referred to the strongest image of all shown in the photographs. This lies a little further from the central one than does the first on the other side of it. On the assumption before stated its wave-length lies somewhere near 3957. This number, of course, is only an approximate one, but the region occupied by the line was obviously so near the boundary of the visible spectrum, that a long series of experiments, in which we called in the aid of photography and fluorescence, was made in order to determine whether an unrecorded hydrogen line existed in that region. All I can say is that the point may be said to be yet undetermined. It is quite true that in several vacuum tubes which Dr. Schuster and myself employed, a strong line more refrangible than H was seen, but then these same tubes unfortunately showed us lines in the visible spectrum, which beyond all doubt did not belong to hydrogen. The elimination of impurities is such a delicate matter, and one requiring such a large expenditure of time, that our report was sent in leaving this point *sub judice*. We tried hydrogen at atmospheric pressure in order to get such a predominance of the hydrogen vibrations as to mask the impurities, but this did not serve us, for the continuous spectrum was so bright in the violet and ultra-violet as to render observations of lines next to impossible. Owing to many reasons, Dr. Schuster's absence from London being one of them, we have not been able to renew the search.

The near coincidence of this spectral image with the H-line leads us to ask the question whether Young's beautiful work in his mountain observatory might not help us on this point. Young found the calcium lines always reversed in the penumbra and near every large spot. This important statement shows us that calcium is one of the metallic vapours which is most frequently ejected from below into the prominences; it is possible, therefore, that the prominences, the spectral images of which were photographed, may have been due to an eruption of calcium. This, of course, is only a suggestion, but the fact that it is a suggestion merely shows how important it is that this point should engage attention next July. If the prominences are then constituted as they were in '75, this violet line will doubtless turn up again, and that is why I have been most anxious to point out not only the conclusions to which we have been led, but the extreme difficulty of arriving at any conclusion whatever, unless by one method or another we have an absolute comparison of the spectrum of the prominences with that of the sun itself.

---

[1] Continued from p. 483.

I have before referred to the fact of the registration on the plates of a continuous spectrum. If we were to suppose the whole light of the corona to be due to 1474 light, for instance, we should expect to get just as definite an image of the corona in the prismatic camera as in an ordinary one. And if everything outside the moon gave us nothing but a line spectrum, the moon's limb would have a perfectly defined edge. Now as a matter of fact, only one such edge is seen in the photographs. We have only one complete ring with a thoroughly defined hard outline, such as that to which reference has been made. This hard ring corresponds to the second spectral image of the prominences, and is a continuation of it. Supposing we were right about the prominences, the ring would be due to the high temperature *h* line of hydrogen (supposing us wrong it might be a companion line to 1474); as the observations of Respighi, Janssen, and others, in the Indian eclipse of '71 endorsed the American observations of '69 that the hydrogen lines are the strongest in the photographic parts of the corona, we may very possibly be really dealing with hydrogen.

Now the edge of the corona, or the upper part of it considering it as the sun's atmosphere, as seen on our photographs, is precisely such as would be given by homogeneous light; that is, there is a distinct image, and there is one image and not three or any other number. Have we any means of determining the wave-length of the light by which this image has been produced? Let me give an idea of one method which we employed:—A circle of the same size as the image of the moon on a photographic enlargement of the original negative was cut in paper and placed over the enlargement until the corona was symmetrical round it, as we know it to have been symmetrical round the moon's body, or nearly so, at that phase of the eclipse.

We found as a considerable endorsement of the assumption which we made regarding the hydrogenic origin of the chromospheric images, that the paper circle in this position had its circumference coincident with the hard ring to which I have referred as being a continuation of the middle spectral image of the prominences. Next, one of the ordinary photographs of the corona was enlarged to the same size as that of the one produced in the prismatic camera. When these were superposed so that the outlines of both coincided as much as possible, it was again found that the edge of the moon lay along the ring.

Now then for the continuous spectrum. The general woolliness of the photographs which at first sight gives rise to the idea that they were out of focus, and that there is nothing to be got out of them, is of course only in one direction, that at right angles to the edge of the prism employed. There is a well-defined structure running parallel to this direction, which of course is the line of dispersion; this structure is doubtless due to irregularities in the corona, drawn out by the prism into bands; it is easy to determine the limits of this continuous spectrum.

Examining the centre of the photographs we find that on one side the structure stops short at F, on the other it extends to a considerable distance beyond the prominence image in the ultra-violet, spaces of light being visible beyond 3530.

From these data we concluded that the continuous spectrum-giving region extends at least to a distance of $3'$ of arc from the sun's limb. This continuous spectrum is well shown on photographs taken at the beginning and end of the eclipse. One of the plates of the prismatic camera was exposed, until the signal for the end of totality was given. Dr. Schuster states that all the observers agreed that the signal was given rather too late, and the fog on the plate indicates an intense illumination; nevertheless, the edge of the sun is not drawn out into a continuous band but rather into three distinct bands. It is probable, therefore, that when the plate was exposed, only the lower part of the chromosphere had appeared, and that it gave out light of such intensity that everybody imagined that the sun itself had come out of eclipse. I observed this myself in 1871, and a very striking fact it is.

So much then for the results obtained by the prismatic camera in '75. When the report is issued—and its issue cannot be much longer delayed—it will be seen that the hasty sketch I have now given can be followed in greater detail.

One of the most remarkable points about the expedition to Siam was the failure to obtain even spectra of the sun with the ordinary telespectroscopic cameras employed. No doubt the unforeseen delays which left very little time for the adjustment of instruments, have a great deal to answer for. I have little doubt that if the attempt is made next July, when any quantity of skilled help will be at hand, and any amount of rehearsal will be possible, that a full measure of success will be obtained, at all events for the most photographic part of the spectrum. An ordinary photograph of the corona was obtained by Dr. Schuster in two seconds; and my experience with photographic spectra enables me to say that this photograph was taken by means of an almost monochromatic light—that near G. Now as the coming eclipse will enable an exposure of almost 100 times longer than this to be employed, I do not think that the undoubted feebleness of the object need be feared. Besides, this method would enable us to pick up the light of those lower reaches of the chromosphere which, as has been already stated, are of such extreme brilliancy as to have been mistaken, on many occasions, for the sun itself.

Up to the present time no attempt has been made to obtain a photographic record of the polarisation of the corona. The difference of colours indicating radial polarisation observed by me when I used the biquartz in 1871, certainly have left the impression on my mind that it would be quite easy to obtain a permanent record of them. This would be a very valuable result, and one which would set at rest a question which, though I consider it settled in my own mind, is yet, I believe, held to be still doubtful by many interested in these matters.

In what I have written I have touched only upon obvious work suggested by the previous observations. I have little doubt that the preparations of the skilled astronomers of the United States include many surprises and daring attempts among the solid work which we are quite certain of.

All here wish them the extremest measure of success, which I am sure their efforts will do more than command.

J. NORMAN LOCKYER

ATLANTIC SHELLS

Testacea Atlantica; or, the Land and Freshwater Shells of the Azores, Madeiras, Salvages, Canaries, Cape Verdes, and Saint Helena. By T. Vernon Wollaston, M.A., F.L.S. Royal 8vo, pp. 588. (London: L. Reeve and Co., 1878.)

IT is with a saddened feeling we take up our pen to notice this valuable contribution to malacology; for ere its pages had left the hands of the binder, its talented author had passed "into the shadowy land."

The name of Wollaston is connected ancestrally with more than one department of science, and the author of the present work has well maintained the honourable reputation of Dr. Wollaston, the discoverer of palladium and rhodium, and the founder of the Wollaston Medal and Award.

Compelled in 1847 to visit Madeira on account of his health, he commenced to collect the land-shells of the various outlying islands and rocks of the Madeiran Group; and although (as he tells us) insects, rather than mollusca, formed at that time the main object of his researches, he was able to add a considerable number of unmistakably new species to the careful and elaborate catalogue which had previously been compiled by his friend and companion, the late Rev. R. T. Lowe, then chaplain at Funchal, Madeira, and to whom the present work is dedicated.

So interested did he become in the insects and land snails of Madeira, that, although no longer compelled to submit to exile on account of his health, yet he returned again and again to Madeira and spent many weeks under canvas high up among the mountains collecting.

In 1858 he visited the Canaries in the yacht of his friend, Mr. John Gray, and again in 1859. On both these expeditions he was accompanied by Mr. Lowe. He was thus enabled thoroughly to explore the numerous and widely-scattered islands of the Canarian group under the most fortunate circumstances for collecting.

Under the same happy auspices he visited the Cape Verdes in 1866, Mr. Lowe again being his companion. In 1875 Mr. Wollaston sailed for St. Helena with Mr. Gray, where he spent six months in investigating the natural history of that remote little oceanic rock, being on this occasion accompanied by Mrs. Wollaston; the Rev. R. T. Lowe, his friend of many past years, having lost his life in 1874 on his outward voyage to Madeira.

Mr. Wollaston has felt it desirable to place these facts on record, in order to show that the several islands and archipelagos treated of in the volume before us—with the exception of the Azores—had all been visited personally by himself.

Although this book contains descriptions of no fewer than 558 species and varieties of land and freshwater mollusca, the author does not claim for it the position of a monograph, but rather a critical enumeration of all the forms hitherto recorded, with special reference to *habitat* in the several Atlantic archipelagos.

Out of the large number of species and varieties described in this work, there are only twenty-nine which are claimed by the author as *actual novelties;* sixteen of these are from the Canaries, nine from Madeira, two from St. Helena, one from the Salvages, and one from the Cape Verdes. Mr. Wollaston would have conferred a still greater service on his fellow-workers had he given short diagnostic characters of all the species enumerated. This would greatly have facilitated the identification of the various forms and saved the student much time and avoided the necessity of referring in many instances to other works. It is also much to be regretted that references are not given to the excellent published figures of most of the species which are to be found in Reeve's "Conchologia Iconica" and the second edition of Martini and Chemnitz's "Conchylien Cabinet" by Küster. Well-drawn and correctly-coloured figures are almost indispensable for the accurate determination of land-shells where form and colour are dominant characters. It is easy to *see* and identify the form, when carefully delineated, but almost an impossibility to convey it to the mind in words.

Mr. Wollaston has shown throughout the strongest preference for the limitation of species—at times becoming extremely hypercritical—and in some instances he seems to be altogether in doubt as to what constitutes specific rank. For example, under *Helix bicarinata* (*vide* p. 161), he states that he is far from certain that it is more than a phasis of *H. echinulata;* yet a few lines below he observes that he has never found a single example among thousands which could be strictly regarded as intermediate.

Again (p. 209) *Pupa fanalensis,* "this may be only a depauperated state of the var. *β. anconostoma* of the *Pupa umbilicata,* which the latter has gradually assumed through having found its way into the higher regions, nevertheless I believe it to be truly distinct."

It is strange to find a man with Wollaston's admitted talents and vast opportunities for observation struggling hard against the accumulated evidence of more than thirty years, and clinging tenaciously to the last to the doctrine of the immutability of species. Thus in his Summary (p. 561), when commenting on the difficulties which arise in defining what is a "species" and what a "variety," he adds, "these remarks are by no means intended to insinuate that the lines of demarcation between species, when correctly interpreted, are ever, in my opinion, *really* confused or doubtful, the exact opposite having always been my firm belief."

Eliminating what Wollaston calls "the European or more distinctly Mediterranean forms" from the catalogue, so that only "the Atlantic element" remains, "the actual species which range beyond the limits of a single archipelago are marvellously few—about four or five being common to the Madeiras and Azores, about five or six to the Madeiras and Canaries, and about one to the Canaries and Cape Verdes; whilst between the Azores and Canaries there are only about five, and between the Madeiras and Cape Verdes about one. Moreover there are strong reasons for suspecting that some even of these (perhaps, indeed, most of them) may have been accidentally transported amongst the islands, through indirect human agencies, at a comparatively recent date; so that we are driven to conclude that, so far as the absolute *species* are concerned, of which their aboriginal faunas are respectively made up, the groups are practically almost independent of each other. And yet, in spite of this, I have had occasion to insist more than once upon the many characteristic *types* which, under the aspect of totally different but nevertheless allied species, permeate *to a greater or less extent* the entire 'province,' giving to it an amount of *unity*, through its several component parts, which it is scarcely possible not to recognise." (P. 563.)

The "*Atlantis* hypothesis" was clearly present to Wollaston when he wrote:—

> "There may doubtless be many explanations, perhaps equally plausible, of these phenomena, but I must confess that none commends itself so thoroughly to my mind as the possible breaking up of a land which was once more or less continuous, and which had been intercolonised along ridges and tracts (now lost beneath the ocean) which brought into comparatively intimate connection many of its parts, even whilst others, though topographically near at hand, were separated by channels which served practically to keep them very decidedly asunder. It is on some such principle as this that I would account for the Canaries appearing to be not only as widely removed from Madeiras as perhaps even the Cape Verdes are, but (whilst further to the south) *to possess a fauna of which the 'Mediterranean' element is much more traceable.* This latter circumstance, which is shadowed forth likewise by the Coleopterous statistics, is by no means a fanciful one, whole groups which are indicative (more or less) of Mediterranean countries, but which have no single representative elsewhere in these Sub-African archipelagos, being quite at home at the Canaries." (P. 565.)

An evolutionary phase of mind must have prevailed with Wollaston when he penned the following sentence:—

> "It is quite clear that the depression of certain tracts, and the upheaval of others, would produce an amount of disturbance in the fauna which could not fail to show itself *in some one way or other* which would afterwards become more or less decipherable; and I cannot conceive much difficulty in picturing the kind of change which might be brought about by the isolation of a cluster of individuals on a small rock, destined henceforth to become the habitat of a race which would, we may feel well nigh certain, rapidly mature for itself *some* slight distinguishing mark." (P. 566.)

But he quickly returns to his former state, and adds:—

> "Considering how unmistakable the evidence is for the variability (in this particular sense) of many of the Atlantic types—a 'variability' so decided that a slightly different phasis has been assumed in certain of the Archipelagos, for nearly every separate island and isolated rock, it may sound, perhaps, somewhat paradoxical to speak, nevertheless, of their apparent freedom from further change; and yet if there is one fact more distinctly shadowed forth than another it is, without doubt, their *present stability.*" (P. 566.)

Further on he continues:—

> "After the most rigid and conscientious inquiry, I am bound to add that the 'developments,' so called, which might well be supposed to have been slowly elaborated, are (if any) simply *inappreciable.*" (P. 567).

However widely we may disagree with Mr. Wollaston's conclusions on the *quæstio vexata* of species and varieties, his critical remarks are of great importance from the large series of specimens examined by him, and the fact that the types themselves were, in many cases, in his possession.

In an admirable lecture "On Insular Floras," by Sir Joseph Hooker, delivered before the British Association at Nottingham in 1868, he described the Madeiran flora as composed of two elements, the one clearly allied to that of the shores of the Mediterranean, the other totally different, and allied to none other but what is found in the Canaries and Azores, which he designated "the Atlantic Element."

That Sir Joseph Hooker's researches on the flora and Wollaston's observations on the insect and molluscan fauna of these Atlantic islands should bring out precisely similar results, will seem the less surprising when we remember the direct connection and interdependence existing between plants and insects, the latter acting as the great fertilising agents to the former; whilst the dependence of land snails upon plants is equally manifest.

All the difficulties raised by Wollaston as to the rare, peculiar, and isolated forms described by him were met and answered by Sir Joseph Hooker ten years ago. Assuming these minute islands to be relics of an older and once larger land-area which had been gradually reduced by subsidence, he pointed out that such a change, by contracting the area would intensify the struggle for existence. He showed that they were not new forms likely to increase and multiply, but rather old forms dying out. Also that in this exterminating process man was even a more destructive agent than the subsidences of land. For instance Madeira when discovered was so densely wooded that the settlers set fire to the forest and the fire raged for seven years, no doubt exterminating many species and reducing the number of others proportionately.

In Porto Santo rabbits had proved even more destructive than man; whilst in St. Helena, the introduction of goats in 1513, had almost exterminated the forests and the subsequent replanting of the island with exotic plants prevents the remaining indigenous vegetation from resuming its sway.

Whatever be the extent of area which we reclaim from ocean for our ancient "Atlantis," it is evident that formerly intercommunication existed between the Azores, Madeira, the Canaries, the Cape Verdes, and Southern Europe in Miocene times, for Prof. O. Heer considers some of the *Helices* of Porto Santo to agree with those of the Swiss molasse.

The poet's dream may therefore well be realised by the geologist:—

"Which tells, great pictured Continent, of thee
O blest ATLANTIS! can the legend be

Built on wild fancies which thy name surround?
Or doth the story of thy classic ground
With the stern facts of Nature's face agree?
What if no tongue may tell!—thy halo fair
Still lingers round the isles which slumber there."

("Lyra Devoniensis," p. 135).

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Indian Rainfall

As Dr. Hunter has been good enough to mention my name in his letter to NATURE (vol. xvii. p. 59) in connection with a comparison of the rainfall of Northern India and the sun-spot period, I may, I trust, be allowed to express my opinion regarding the validity of some of the conclusions he draws therefrom. In the first place I would remark that Dr. Hunter's idea of the *winter* rainfall of Northern India being due to the *immediate rebound of the summer monsoon* from the Himalayan barrier is at variance with facts in the meteorology of the country. The rebound ought to take place directly the monsoon vapour-current impinges upon the Himalaya, *i.e.*, in the *summer*. In fact, it is by a succession of oblique rebounds from this impassable barrier that the monsoon is gradually reflected towards the N.W.P. and the Punjab.

The *winter* rains, on the contrary, have nothing to do with the monsoon, being, as is well known, due to a branch of the anti-trade, which, descending in the Punjab, is deflected by the Himalayas towards Behar and Bengal, occasionally reaching Calcutta, lat. 22° 35′ N.

Now between the rains of the summer monsoon and those of the anti-trade (or anti-monsoon as it is occasionally called), there is a well-marked interval of bright, clear, settled weather for two or three months throughout Northern India. After this interval the skies again become clouded, and about Christmas, or shortly after, the gentle but soaking rain of the cold weather sets in, and is repeated at intervals up to the end of March. It is evident, therefore, that the two currents, monsoon, and anti-trade, are totally unconnected with each other; and hence arises the desirability, especially in a question like the present, in which its secular variations are being discussed, of completely separating the rain of the former from that of the latter vapour current. I cannot but think that it is his omission to allow for these vapour currents that has led Dr. Hunter to offer such an erroneous explanation of the results obtained. According to him, copious precipitation should take place in the interval (October to December) between the two seasonal falls, during which clear weather is invariably present. It may be added that the period (December to April) which I took to comprise the winter fall, commenced after this interval.

The real explanation of the direct variation of the summer, and the inverse variation of the winter rainfall of North India, with the sun-spot period, is the hypothesis which first led to its verification coincidently and independently, by Mr. Hill and myself.

To enter upon a complete exposition of this hypothesis would occupy too much of your valuable space, but as it has been found to explain most of the anomalies which have hitherto proved such powerful obstacles (especially in extra-tropical regions) to the universal extension of the theory of sun-spot influence (I use the term advisedly) on the different elements of terrestrial meteorology, I will here briefly indicate its general outlines for the benefit of other workers in the same field of investigation.

The hypothesis, to start with, assumes *the solar radiation to vary inversely with the sun-spot frequency*.

It then takes account of the probable effects of such a variation upon the vapour-bearing currents throughout the globe with respect to velocity, direction, season, and latitude. According as trade, anti-trade, monsoon, or anti-monsoon, prevail (1) at different places at the same season, (2) at the same place at different seasons, so will specifically distinct effects arise both from the amount of vapour brought and its conditions of precipitation, to determine which, not only the general conditions introduced by latitude and season, but the local and peculiar meteorological functions of the region must be carefully studied.

Now as the principal effect of a secular change in solar radiated heat must be to cause a similar direct secular change in the normal convection currents of the atmosphere, we may expect the tropical trade-wind and monsoon regions to furnish us with some evidence, whether direct or indirect, in favour of the above hypothesis.

Little direct evidence has at present been adduced besides that given by Mr. Hill from a comparison of wind velocity in the N.W.P. (NATURE, vol. xvii. p. 505). A good deal of indirect evidence, however, is furnished in the monsoon regions by the occurrence of abnormal droughts and floods in contiguous districts (the drought in the N.W.P. and floods in Assam and Burmah last year were good examples of this kind) at the time of minimum sun-spot, when the velocity of the current being increased it travels in a more contracted channel, and, by a more equable distribution of rain at the time of maximum sun-spot, when the velocity of the current being decreased, it is more liable to extend laterally. In the trade-wind regions similar evidence is furnished by the fact of a deficiency of rain and cyclones at the time of minimum sun-spot, with a corresponding excess of both at the time of maximum sun-spot. The augmented velocity of the wind currents at the former epoch, preventing the formation of local areas of condensation and precipitation, and therefore (according to Messrs. Blanford and Eliot's theory of cyclone generation) of cyclones and their accompanying downpours; while the diminished velocity at the latter epoch favours the same.

Finally, the anti-trade which in its seasonal shifts north and south traverses the entire temperate zone, in the winter bringing rain to North India, Palestine, Madeira, California, &c., and in the summer to Northern Europe and Siberia, should give signs of a secular change in intensity and humidity, corresponding according to the hypothesis inversely with the sun-spots. In the summer, when large continental areas like Europe are more immediately under the direct influence of solar heat, local convection currents being set up will tend to disturb and complicate the effect of any general change in the strength of the anti-trade. In the winter, on the other hand, the obliquity of the incidental solar rays leaves the anti-trade in undisputed possession of the field. At this season, therefore, there should be a marked variation in the rainfall of the temperate zone, more particularly in those regions between 25° and 40° N. and S. lat., where the rainfall of *this season* is the chief rainfall of the year, corresponding *inversely* with the sun-spots. Even in those regions where the rain falls at all seasons, if we pick out the winter from the total annual falls, as was done by Mr. Draper, for New York (NATURE, vol. xvii. p. 15) in accordance with Mr. Hill's admirable suggestion (vol. xvi. p. 505), the results favour the hypothesis. But they do this in a far more marked manner where the rain of the entire year falls during the winter months, as in the Mediterranean and at Jerusalem, which have consequently hitherto been considered by Dr. Jelinek and Mr. Meldrum to afford strong evidence against the theory of a direct connection between rainfall and sun-spots. The inverse variation of the winter rainfall of Northern India is only another example of the same law, and shows how extremely important it is to analyse the seasonal variations separately before deciding the question by a mere cursory glance at the *total annual* falls. The apparent anomalies which Dr. Hunter finds presented in the North American rainfalls are, I think, due to his having compared the total annual falls. If he and other investigators will only take the hint dropped by Mr. Hill, and which I cordially endorse, of comparing the seasonal falls separately, they will find, I think, that while the summer rainfalls of the temperate zone show either a non-periodic variation, or symptoms of one coinciding directly with the sun-spots, the *winter* falls will in general show unmistakable signs of a variation coinciding *inversely* with that of sun-spot frequency and area.

E. D. ARCHIBALD

Sun-spots and Rainfall

I HAVE read with much interest Dr. Meldrum's paper on Sun-spots and Rainfall in NATURE (vol. xvii. p. 448), particularly that part of it in which Dr. Hunter's method of discussing the rainfall of Madras is criticised, and a method of inquiry in sun-spot researches is proposed. This method is, so far as I am aware, a new one, and as such, is deserving of careful examination as to how far it is applicable to the data submitted for discussion.

Dr. Hunter published the data for discussing the rainfall at Madras during the six sun-spot cycles, ending 1876, these being all the available data for Madras. As regards the sun-spots, we certainly have no *positive* data earlier, at least, than these cycles, whatever value may be attached to the approximate earlier figures supplied by Dr. Wolf. As regards, therefore, both the elements under discussion, viz., the sun-spots and the rainfall, the period discussed by Dr. Hunter represents the whole of the cycles for which material is available.

In dealing with this period, Dr. Hunter divides it into six equal cycles of eleven years each, this being substantially the average duration of the sun-spot cycles. I have arranged the relative numbers published in Wolf's last list (*Wolf. Astronomische Mittheilungen*, pp. 35-37), according to the cycles adopted by Dr. Hunter, with the result that all the six minimum years of sun-spots occurred either in the first year of the cycle, or in one of the immediately adjoining ones on either side of it, viz., in the second or in the eleventh years. As regards the years of maximum sun-spot, five out of the six occurred in the fifth or sixth years of the cycle, and the remaining year of maximum sun-spots occurred in the eighth year.

In his paper Dr. Meldrum states that as the sun-spot cycles are not all of the same length, it is evident that, by starting from any one year and going backwards over a long period, always using the same fixed number, a maximum and a minimum year might fall into the same group, and it was to obviate the occurrence of this contingency which the above analysis of Dr. Hunter's method shows did not occur during the period discussed by him, that Dr. Meldrum has proposed his new method as a more accurate mode of discussing the data.

To test the value of this new method of inquiry, I have arranged Wolf's relative numbers of sun-spots in accordance therewith, the maximum year of sun-spots of each cycle being placed in the sixth year, the minimum years being marked with an asterisk, and the "mean cycle" of eleven years being calculated from the thirteen years in the manner described by Dr. Meldrum: –

Year.	811-23	824-36	1832-44	1843-55	1855-67	1866-77	Mean	Mean cycle.	Year of cycle.
	1·6	8·1	26·3	*13·1	7·7	31·4	14·7		
	4·9	16·2	*9·4	19·3	*5·1	14·7	11·6	14·0	
	12·6	35·0	13·3	38·3					
	16·2	51·2	59·0	59·6	56·2	36·8	46·5	48·8	3
5	35·2	62·1	119·3	97·4	90·3	73·6	80·5	77·0	4
6	46·9	67·2	136·9	124·0	94·8	131·8	100·4	91·1	5
	39·9	67·0	104·1	95·4	77·7	111·8	83·0	83·0	6
	29·7	50·4	83·4	69·8	61·0	99·7	65·7	65·6	7
	23·5	26·3	61·8	63·2	45·4	67·7	48·0	49·0	8
	16·2	*9·4	38·5	52·7	45·2	43·1	34·2	34·6	9
	6·1	13·3	23·0	38·5	31·4	18·0	21·0	24·6	10
	3·9	59·0	*13·1	21·0	14·7	11·3	20·5		
13	*2·6	119·3	19·3	7·7	*8·8	*7·0	27·5		

It will be seen from this table that with this arrangement the year of minimum sun-spots has occurred on the tenth, twelfth, thirteenth, first, second, and third years. By Dr. Hunter's arrangement the minimum years fell within a compact group of three consecutive years out of a cycle of eleven, whereas by Dr. Meldrum's arrangement they are scattered over seven years out of a cycle of thirteen. Further, I find that in the second cycle what is virtually a maximum year (viz., 1836 with 119·3 of sun-spots) fell within his minimum group, or in the thirteenth year. This is precisely the result which the method was designed to avoid, but as to the occurrence of which there was not an approach under Dr. Hunter's arrangement.

Again, if the same relative numbers of Wolf be arranged as Dr. Meldrum proposes, so that the year of minimum sun-spots of each cycle be placed in the ninth year of the thirteen years, it will be found that the maximum years are scattered over the twelfth, thirteenth, first, second, third, and fifth years of the series. By Dr. Hunter's method of arrangement five out of the six maximum years fell in the fifth and sixth years of the series, while the remaining one fell in the eighth year, thus again presenting a compact group, whereas Dr. Meldrum's method scatters them over more than half of his series of thirteen years.

An objectionable feature of this new method is the necessary repetition of figures which it involves. Thus, in the table given above, embracing six cycles, nine minimum years occur; and in he table in which all the minimum years are so arranged as to stand in the ninth year of the cycle, nine maximum years also occur, so that if the Madras rainfall were discussed by this method, the averages would be computed from tables in which he maximum and minimum years occur eighteen instead of welve times.

Mr. Meldrum's method might be improved if he entirely struck out the first and thirteenth years of the thirteen years series, and simply "bloxamed" the remaining eleven years for the years of his "Mean Cycle;" that is, made the first of these years the mean of the eleventh, first and second; the second year the mean of the first, second and third. Even, however, with this change the method is inferior to that mployed by Dr. Hunter, and the force of this statement will be the more readily recognised if it be kept in mind that we have no *positive* data from which the relative numbers of the sun-spots can be calculated prior to the time when Schwabe began his great work of sun-spot observation.

Edinburgh, April 22 ALEXANDER BUCHAN

Trajectories of Shot

MR. NIVEN was perfectly welcome to make use of my experiments and tables, as he has done, in trying to devise new methods of calculating trajectories of shot. And when he had satisfied himself that his methods possessed some advantages over others, he required no excuse whatever for their publication. But I altogether object to Mr. Niven's rule for finding v_β being connected in any way with the mode of calculation adopted by me. I beg, therefore, to place side by side Mr. Niven's rule, to which I object, and my rule, which I make use of, and so leave the matter. Mr. Niven says respecting v_β:—

"The first steps in our work must be to guess at it. The *practised calculator* can, from his experience, make a very good estimate. Having made his estimate he determines k. He uses the value of k in equation (a), and if he gets the velocity he guessed at, he concludes that he guessed rightly, and that he has got the velocity at the end of the arc. If equation (a) does not agree with him he make another guess, and so on till he comes right."

The following is the course I pursue to find v_β. Refer to the table of coefficients and take out the value of k_α corresponding to the initial velocity v_α. Substitute in equation (a) and find a *first* approximate value of v_β. Now determine the mean value of k between v_α and v_β just found, substitute in equation (a), and thus find a *second* approximate value of v_β, which will generally be found sufficient. Otherwise adjust by proportional parts.

In this way the value of v_β is found accurately on the supposition that k has remained constantly at its mean value between v_α and v_β. Here the operations are of the simplest kind, and no guessing or practised calculator is required. And with a view to diminish the tedium of making these calculations, tables of $\Sigma\,(k)$, $\Sigma\,(k \div g)$, $(1000 \div v)^3_\alpha$, &c., have been calculated and printed, but their publication has been delayed on account of the experiments proposed to be made with low velocities.

Since Mr. Niven described the process of guessing as "*extremely* dangerous," there can be no doubt that the epithet was "extreme." As I supposed, he is not prepared to supply me with a single practical case where his condition of danger is satisfied. And if a case cannot be found then the objection falls to the ground. Whether we consider the range of values of k for spherical or ogival-headed shot, for velocities above 1,200 f.s., we shall find that $\frac{dk}{dv}$ lies between the limits 0 and $-0{\cdot}09$, or, where k is a mean over an arc, between 0 and $-0{\cdot}05$ about. And it is the smallness of this tabular value which renders it difficult, if not impossible, to satisfy Mr. Niven's condition of danger. But if this quantity had not been small, then the cubic law could not have been used even approximately. Mr. Niven is at liberty to take shot of any size used in practice, moving at any attainable velocity beyond 1,200 f.s., and the coefficients of resistance for either spherical or ogival-headed projectiles. The objection is Mr. Niven's, and he must take the onus of supporting it if he still thinks it of value.

I regret to have to write anything in opposition to Mr. Niven's paper, because in all other respects it appears to me a valuable contribution to the science of ballistics. F. BASHFORTH

Minting Vicarage, April 17

After the first impulse this extreme electro-negativeness of the selenium, due partly to polarisation, gave way and it gradually passed again to the electro-positive side, where, after a few minutes, it settled to a constant value, but still electro-negative to its condition in the dark.

I found that the slightest shadow or other variation in the intensity of the light caused a considerable variation in the electromotive force of the couple and a consequent indication.

On excluding the light the selenium instantly increased in electro-positiveness, and soon settled to its original position.

A couple in which two plates of selenium were opposed to each other, light being excluded from one and admitted to the other, gave identical results, only the resistance of the element was much greater.

The effect of light, therefore, in modifying the surface tension of selenium is evidently to render it more electro-negative and presumably not more metallic, as has been suggested in explanation of its increased conductivity.

I am endeavouring to construct a combination of selenium elements which, with a mirror galvanometer and photographic arrangement may be used to give a trustworthy record of the intensity of daylight. The practical difficulties in the way at present I have hopes will not be insurmountable. ROBERT SABINE

NOTES

WE regret to notice the death, on the 18th inst., of Dr. Thomas Thomson, F.R.S., for some years Superintendent of the Botanic Gardens at Calcutta, and joint author of Hooker and Thomson's "Flora Indica." He was also a contributor to Sir J. D. Hooker's "Flora of British India," now in progress.

THE following are the names of those whom the Council of the Royal Society have recommended for election on June 6 next as appointed:—J. G. Baker, F. M. Balfour, Rev. T. G. Bonney, Prof. J. H. Cotterill, Sir W. Elliot, Canon W. Greenwell, T. Hawksley, C.E., J. Hopkinson, D.Sc., J. Hughlings Jackson, M.D., Lord Lindsay, P.R.A.S., S. Roberts, E. A. Schafer, H. Sprengel, G. J. Symons, and C. S. Tomes.

THE scientific world has sustained a loss by the decease of the Rev. James Booth, LL.D., F.R.S., Vicar of Stone, near Aylesbury, which occurred on the 15th inst., at the age of seventy-one. He was educated at Trinity College, Dublin, where he obtained several prizes and graduated in honours. He was elected a Fellow of the Royal Society in 1846, to a very great extent in recognition of his earliest publication, "A New Method of Tangential Co-ordinates," and also as the inventor of a new system of parabolic trigonometry. In 1852 and 1853 he contributed to the *Philosophical Transactions* two memoirs on "The Geometrical Properties of Elliptic Integrals." He was also known as the contributor of several papers on mathematical subjects to the *Philosophical Magazine*, and not a few of these, we believe, have found their way into other languages. In 1859 he was presented to the living of Stone by the Royal Astronomical Society, to whom the advowson belongs.

DR. FREDERICK KAMPF, who has been the astronomer of Lieut. Wheeler's U.S. exploring expedition, died in Washington, on March 30, at the age of thirty-six. Dr. Kampf was educated at Bonn, and emigrated to the United States in 1870, securing a position in connection with the United States Coast Survey until 1873, when he joined the party of Lieut. Wheeler as already mentioned. He promised to attain to much distinction as an astronomer and observer, and his untimely death is much to be lamented.

THE collection of shells of the late Dr. P. P. Carpenter, of Montreal, is for sale. The opportunities of Dr. Carpenter for making this collection of desirable specimens were very great, especially from the great Reigan collection of Mazatlan shells, which he purchased many years ago, and after investigation deposited duplicate series in several museums in Europe and America. The collection embraces about 4,000 species and varieties, for the most part original types. The collection is deposited for the present in the museum of M'Gill College, Montreal.

DR. RUD. FALB, of Vienna, who is engaged in studying the earthquake region in South and Central America, has left Chile and announces his arrival at Arequipa. He intends to ascend the volcano of Misti, near Arequipa, which is some 17,600 feet in height. He also reports that at the southern part of the Peruvian coast the shocks of earthquake continue with unabated violence, and that a violent eruption occurred recently from the Cotopaxi Volcano in the Andes of Quito, without, however, doing much damage.

AN Ethnographical Congress will assemble in Paris on June 24, and continue for three days. The head-quarters of the Commission are rue Monsieur, 19.

The Chair of Surgery at the Collége de France, occupied by the late Claude Bernard, has been offered to Prof. Charrot. It has been decided to erect the statue of the distinguished physiologist immediately before the Collége de France.

DR. E. BAUMANN, one of the most promising of the young physiological chemists of Germany, has received a Professorship in the Berlin University.

WE notice the death of Prof. H. Girard at Halle, on April 12. He was, until a recent date, director of the Mineralogical Museum of the University of Halle, and his name is associated with several mineralogical researches, more especially in connection with the Stassfurt deposits.

AMATEURS of spectrum analysis will thank Mr. Browning for a little pocket case he is now selling which permits a study of absorption phenomena in a very satisfactory manner. Various substances, which give very characteristic band absorption, have been mixed with gelatine so as to form a thin transparent coloured film. In that we have received, roseine, eosine, cochineal, indigo, aniline blue, Hofmann's violet, and other colouring matters have been treated in this way. There are twelve differently coloured films in all, and the variations in the spectra are very striking. On holding the films horizontally close to the slit so that one film falls on the upper and the next on the lower part of it, a capital idea of the use of comparison spectra can be gained.

M. DABRY DE THIERSANT, a French *Chargé d'Affaires*, who has been instrumental in introducing a number of Chinese plants and animals into his native country, is now making arrangements for importation in quantities of the *sets*, one of the most valued fish found in Chinese waters. The fish belongs to the carp family, and when fed on sea-plants in ponds, attains with great rapidity a weight of about forty pounds. During the past three years experiments made on the fish in the Jardin d'Acclimatation have shown it to be well adapted to a European climate, and as it increases rapidly, it is hoped that within a few years it can be introduced extensively throughout Europe.

A LITTLE village in the neighbourhood of Draguignan, France, has lately been the scene of a remarkable subsidence which has attracted the curious from all directions. An elliptical tract of ground, containing over 10,000 square feet, sank gradually one day, accompanied by loud noises, until it left an orifice of over 100 feet in depth, with water at the bottom. Numerous trees and vines disappeared completely in the depths of the new lake. A similar depression on a smaller scale occurred in the same vicinity a century ago, and both the phenomena are attributed to the action of subterranean streams.

THE Central Society of Agriculture of France took possession, on March 13, of a splendid hotel which has been built for its use and presented to it by M. Behague, one of its most active members. This society is one of the oldest in Europe, having been established more than a century ago, under the reign of Louis XV. It has never been suppressed or interrupted in spite of the several changes and revolutions the French Government has undergone during that eventful period.

THE International Congress of Medical Sciences, which was to be held at Amsterdam in September, 1878, has been postponed to 1879, in order to avoid a coincidence with the Paris International Exhibition.

M. BARDOUX, the French Minister of Public Instruction, having established an observatory for astronomical and meteorological purposes at Besançon, the general council of the Doubs department have voted a sum of 5,000 francs for meteorological observations to be conducted in the building.

THE private view of Winkler's Lunar Landscape, which we recently described, will be on Saturday and Monday next, at the new premises of the Belgian Gallery, 112, New Bond Street. The picture will be lighted by artificial light, this having been found to be most suitable to the nature of the subject.

KEW GARDENS were opened to the Public on Easter Monday at 10 A.M., and will be opened at the same hour on future bank holidays. Of the necessity of this step some idea may be formed from the following statement of the number of visitors on Monday:—From 10 to 1, 3,352; from 1 to 7, 42,833; total, 46,185.

MACMILLAN AND CO. are about to publish a little manual of "Practical Chemistry, for the Use of Medical Students," &c., by Mr. M. M. Pattison Muir, of Caius College, Cambridge.

A TERRIBLE hurricane is reported to have occurred at Tahiti, on February 7, in which 120 persons were killed, and much property destroyed.

HITHERTO we have had no occasion to say anything concerning the disturbances in the East, but during the past week there was a commotion at that now historical place St. Stefano, which we cannot let pass without reference. Happily the commotion was only seismic and did no damage. It occurred on Friday evening last and was strongly felt at Pera, while at Ismid and Broussa damage is said to have been done. The sea in the neighbourhood of the British fleet was so agitated that the commander of a gunboat sent a request to Admiral Hornby to give him previous notice on the next occasion of torpedo practice.

IN connection with our recent note on chemical dictionaries we notice the completion of the second volume of the German "Handwörterbuch der Chemie," ending with the article on Electricity from the pen of Prof. Wiedemann, of Leipzig.

AT a recent meeting of the French Academy, M. Gaiffe presented an apparatus with which one may determine immediately, and by a simple reading, the electromotive force of any electro-generator. It is based on Fechner's method of measuring such forces, and the measures are read in volts. M. Gaiffe employs a very resistant multiplier, and a small rheostat, by means of which introducing resistances, greater or less, into the circuit, the instrument may be adapted for very different measures of electromotive force, the same divided scale, however, being always employed. On introducing such and such a resistance you divide or multiply, in a proportion marked on the contacts of the rheostat, the electromotive force indicated by the galvanometric needle. Forces may thus be measured by the instrument from $\frac{1}{10}$ volt up to 150 volts.

J. E. PEIJSMANN has just published, in Batavia, an account of a scientific tour through the island of Amboina, one of the most important spice islands in Malaysia. In addition to a variety of valuable and novel observations, M. Peijsmann collected over 1,000 varieties of plants and 300 specimens of the fauna, which are to be transmitted to the museums of the University of Leyden.

A NEW bridge across the Rhine is now in course of construction at Basel; it will rest on five pillars.

THE Dutch Government intends to construct a canal from Amsterdam through the so-called Geldern Valley to the Upper Waal (the southern branch of the Rhine), and also additional canals in the provinces of Drenthe and Overijssel. Both projects are of great commercial importance with regard to navigation on the Rhine and the communication by water between Germany and Holland.

DR. SCHOMBURGK, the director of the Botanic Garden, Adelaide, South Australia, has issued a very brief report relative to the economical value of the various species of South Australian "Eucalyptus." He shows that out of the large number of species of Eucalyptus spread over Australia and Tasmania, only thirty appear in the extra-tropical part of South Australia. The South Australian species do not reach so great a height as those of the east, north, and south, and only about ten species yield timber that is much valued and used, though Dr. Schomburgk thinks many more might be utilised. The most valuable timber in the colony is stated to be the red gum (*Eucalyptus rostrata*, Schlecht). It is the most durable of all the South Australian woods, and is mostly used for underground work, bridges, jetties, railway sleepers, and for shipbuilding; moreover, it has the reputation of being proof against the attacks of white ants. This tree grows to a height of from 100 feet to 130 feet. The next most important species is the white gum (*Eucalyptus stuartiana*, F. Muell.), the blue gum (*E. viminalis*, Las.), and the stringy bark (*E. obliqua*, L'Herit.). Dr. Schomburgk points out that the woods are not the only useful products of the Eucalypti. From *E. obliqua*, *E. leucoxylon*, and *E. rostrata*, acetic acid is obtained; wood-spirit is also procured from the first two, essential oils are produced from the leaves of *E. vincinalis*, *E. stuartiana*, and *E. citriodora*; tar from woods of *E. rostrata*, *E. leucoxylon*, and *E. obliqua*; and from the barks of several other species paper has been made.

IT is announced by M. Tosselli, that through successive improvements of his refrigerating apparatus, he can now produce one kilogramme of ice in the space of two minutes.

THE announcement of the intended publication, in a short time, by the Smithsonian Institution, of a complete catalogue of the plants of North America, will be hailed with great satisfaction by botanists. The region covered extends from Greenland and the Arctic Ocean, on the north, to the borders of Mexico, and from the Atlantic to the Pacific. The species are enumerated in their systematic sequence, with their synonyma. The work will be published in two parts, the first, on the polyptalæ, constituting a volume of about 480 pages. It covers the ground of volume i. of Torrey and Gray's "Flora of North America." The title of the work will be "Bibliographical Index of North American Botany," by Sereno Watson.

THE increase of volume of liquids through absorption of gases has lately been investigated by Messrs. Mackenzie and Nichols, in the Physical Laboratory of Berlin University. Experimenting in the first instance with carbonic acid and water only, and employing two different methods, they reach the same result, viz., that the expansion is directly proportional to the quantity of gas absorbed. They further examined the expansion of water saturated with carbonic acid by heat, and got a curve having

The Earliest Changes in Animal Eggs.—The patient researches of van Beneden, Grieff, and Oscar Hertwig have discovered many interesting facts in the structure of simple ova when laid, the mode of fertilisation, and the first segmentation. Oscar Hertwig's last observations are on the starfish Asteracanthion (*Morphologisches Jahrbuch*, vol. iv. Part I.), and he describes the changes as follows:—The germinal spot of the unfertilised ovum first shows a separation into two portions, while part of the germinal vesicle contributes material out of which first one and then a second "directive corpuscle" is formed. By this time the germinal vesicle is undistinguishable, having left a small portion as the ovinucleus (*eikern*). When fertilisation takes place, the spermatozoon gives rise to a small body, the sperm-nucleus (*spermakern*); this body approaches the ovinucleus, and they fuse to form the segmental nucleus (*furchungskern*); this precedes the division of the whole egg into two cells. If such observations are extended to many species and confirmed by other observers, we shall have an important gain in our knowledge of the results of fertilisation.

Glacial and Post-Glacial Fishes of Norway.—We learn from the Danish *Naturen* the appearance in the third part of the *Nyt Magazin for Naturvidenskaberne*, of a paper, by M. Robert Collett, on the glacial and post-glacial fishes of Norway. These fishes, which are most perfectly preserved in chalk-lumps, the outer shapes of which more or less perfectly exhibit the outer shapes of the included fishes, are found in clay deposits some 360 feet above the sea; the fishes belong all to the existing fauna, displaying at the same time their Arctic and North Atlantic origin. Out of twelve species, described by the authors, the most common is the *Mallotus villosus*, which is found everywhere; one species, the *Clupea sprattus*, is worthy of notice, because it is now a native of more southern waters.

Poaching Birds.—Mr. N. B. Moore has made observations at the Bahamas on the *Certhiola flaveola*, which obtains nectar from the flower of *Verea crenata* by thrusting its bill at once through the petals into the nectary. It is only after the bird has made an opening that small black ants and other small insects are found in the nectary. But these birds also poach on the woodpecker's preserves. One day Mr. Moore observed a *Picus varius* extracting sap from a logwood sapling, and as the woodpecker flew away, two Certhiolæ appeared, perched near the sap-pits from which the juice was oozing, and by cunningly thrusting in their penicillate or bristle-tipped tongues, commenced to lap or suck the fluid into their mouths. This practice was constantly observed afterwards. Mr. Moore fixed the bowl of a teaspoon in a fork of the same tree, and placed some strained honey in it. In three days the Certhiolæ found this, and commenced to feed on it. They were followed by another bristle-tongued bird, *Dendrœca tigrina*, and other species, who also attacked the woodpecker's sap-pits. These are interesting instances of apparent intelligence on the part of birds (*Proc.* Boston Soc. Nat. Hist., January, 1878).

GEOLOGICAL TIME[1]

If a rigid body be in rotation about an axis of symmetry it will continue to rotate about that axis, but if it be set spinning about an axis inclined to that of symmetry the axis about which it spins will be continuously displaced relatively to the body; in other words, it will wabble.[2] This wabbling is well illustrated by the motion of a top whilst it is "going to sleep."

As the rotating body approaches more and more nearly the spherical shape, so does the wabbling become slower and slower. If the earth, which is nearly spherical, were to wabble in its diurnal rotation it would do so in about 305 or 306 days.

Dr. Haughton has lately published[1] an ingenious speculation, founded on the possibility of the wabbling of the earth, in which he seeks to determine limits to the duration of geological time from the observed absence of any motion of this kind.

The object of the short paper, of which I am here giving an account, was to combat the applicability to the case of the earth of Dr. Haughton's results.

The method pursued by him may be shortly described as follows:—If a continent were to be suddenly upheaved the earth's axis of figure (or strictly speaking, the principal axis of greatest moment of inertia) would be displaced from its previous position; immediately after the earthquake, the axis of rotation being where it was just before the earthquake, is no longer coincident with the axis of figure, and therefore a wabble is set up in the earth's motion. If it were not for frictional resistances that wabble would continue for ever after. But it is easy to see that, as the ocean is not rigidly connected with the earth, a tide of 306 days period would be set up. This tide would then rub on the sea-bottom, and would gradually reduce the wabble and bring the earth "to sleep" again like a top.

By reference to the estimate of Adams and Delaunay of the effects of tidal friction in retarding the earth's rotation, Dr. Haughton endeavours to find a numerical value for the frictional effect of such a 306-day tide as above explained. He then finds how long it would take to reduce a wabble of given amount to one of any smaller amount.

In a previous paper he had already shown that the elevation of the continents of Europe and Asia must have shifted the earth's axis of figure by 69 miles at the earth's surface. If, therefore, such an elevation took place suddenly, it must have started a wabble, in which the axis of rotation described a circle of 69 miles radius round the axis of figure.

But Dr. Haughton is of opinion that astronomical instruments are now so perfect, that a wabble of 5 feet in radius would be detected, and that it is not, therefore, permissible to suppose that the present actual wabble has a radius of even 5 feet. His numerical calculations, then, show that it would take 641,000 years to reduce the radius from 69 miles to 5 feet by means of the tidal friction, and he, therefore, concludes that, if Europe-Asia were manufactured *per saltum*, that event cannot have taken place less than 641,000 years ago, and that it may have been at a much more remote epoch.

The improbability of this supposition induces him to consider the case of elevation by 69 geological convulsions, each of which displaced the axis through one mile, and where the radius of the wabble is reduced to five feet between two successive convulsions. He here finds that the elevation of Europe-Asia must have occupied 27½ million years, and that no geological change altering the position of the earth's axis through one mile can have taken place within the past 400,000 years.

He lastly supposes that the wabble has a radius of 5 feet, and that the geological changes take place at such a rate that the increase of the radius is exactly destroyed by friction during each wabble, so that the radius of 5 feet remains constant. On this supposition he finds that the time required was 4,170 million years.

Now it appears to me, from this method of treatment, that Dr. Haughton is of opinion that a second earthquake of elevation following a first would necessarily increase the radius of the wabble. For if not, why does he postulate a lapse of time between successive earthquakes, and in the last case make the supposition of the increase of radius be exactly destroyed? It is on this point that I venture to differ from him, for it seems to me, from dynamical considerations, that a second equal impulse following a first, at some time within 306 days, might either double the wabble, alter its amount, or annihilate it, according to how it was timed to take place.

---

[1] Abstract of a paper read before the Royal Society on March 14.

[2] I follow Dr. Haughton in the use of this very expressive word.

[1] Notes on Physical Geology, No. III., *Proc. Roy. Soc.*, vol. xxvi. p. 534.

If I am correct in this view, I cannot but think that the estimate of geological time falls to the ground. For even if the elevation of continents took place impulsively, we can have no possible data for judging of how the earthquakes were timed with reference to the position of the axis of rotation, and unless they were properly timed the radius of the wabble could not increase; and the increase of the radius is, I imagine, essential to Dr. Haughton's method.

But if we set aside the impulsive theory of elevation, the work contained in my paper, "On the Influence of Geological Changes on the Earth's Axis of Rotation,"[1] will be applicable; for I there considered the effects of a slow continuous elevation of continents. In that paper I show that such a mode of elevation would set up a wabble of 306 days' period in the earth's motion. But this wabble is of quite a different character from that contemplated by Dr. Haughton, for it is unsymmetrical, so that the axis of rotation coincides with the axis of figure every 306th day.

By a very simple application of a formula given in that paper, it will be found that, supposing the continuous elevation to take place at such a rate that the axis of rotation is 5 feet distant from that of figure when at its greatest distance, then the axis of figure must be travelling with reference to the solid earth at the rate of $\frac{3}{16}$ of a second of arc per annum. Thus, in 19,200 years it will have travelled over 1° or 69 miles. That is to say, Europe-Asia might have been elevated in 19,200 years without the axis of rotation ever having described a circle of more than 5 feet in *diameter*. If the elevation were then to stop suddenly a symmetrical wabble would be set up (such as that considered by Dr. Haughton), and the *radius* of this wabble could not be greater than 5 feet, and might be zero, according to the exact time of the stoppage.

This investigation makes no reference whatever to the effects of tidal friction, and there are certain considerations which lead me to believe that even the above estimate of time might be largely reduced.

The conclusion at which I arrive therefore is that the elevation of Europe and Asia might have taken place in very much less than 20,000 years without leaving behind any wabbling in the earth's motion traceable by astronomical observations. Dr. Haughton's views, if generally accepted, are of the very greatest interest to geologists, and they therefore merit the strictest examination; as I have devoted a good deal of time to this subject I thought it might perhaps be useful to write this note. Should my present criticism be incorrect, there is little doubt but that it will meet its just fate of refutation.[2]

G. H. DARWIN

EARLY ELECTRIC TELEPHONY

IN 1861 the first successful attempt at the construction of an electric telephone was made by Philip Reis, a teacher in a school at Friedrichsdorf, near Homburg. On October 26, 1861, Reis showed his instrument, which he termed a "telephone," to the Physical Society of Frankfort-on-the-Main; and on that occasion he succeeded in electrically transmitting various melodies, which were distinctly heard throughout the room. In the paper he read before this Physical Society, published in the annual report of the Society for 1861, Reis states:—"Melodies were sung, not loudly, into the transmitting apparatus placed in a hospital some 300 feet away from the audience, care being taken that no sound could be heard, by direct transmission, or by conduction along the wires. The sounds of various musical instruments were clearly reproduced, as the clarionet, horn, organ-pipe, and even harmonium and pianoforte when the transmitter was placed on their sound-boards, provided the tones were within the compass of *f* to F″. Articulation was not reproduced equally well. Consonants, however, were in general pretty clearly heard, but not the vowels." In this report, which is entitled "Telephony by Means of Electric Currents," Reis shows how he was led to the construction of his instrument by a study of the mechanism of the organ of hearing, and of the manner whereby sounds are perceived by the human ear, and he gives a series of diagrams representing the resultant curves that would be produced by the combination of various concords and discords. Thus, he was led to perceive that "if it were possible to create, in any manner, a mode of vibration whose curve resembles that of any tone or chord, then a sensation would be produced similar to that given by the tone or chord itself." This principle, he affirms, guided him onwards.

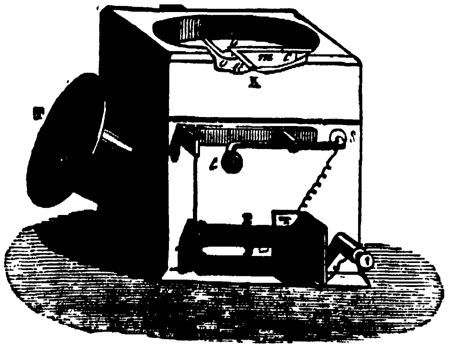

FIG. 1.—This and Fig. 2 show the usual but imperfect form of Reis's telephone. Fig. 1 is the transmitting apparatus. T represents the mouthpiece, *m* the membrane closing the upper portion of the box K, a portion of which is cut away to show the movable lever, *a b c*, resting by a projecting point *b*, on the platinum disc *o*, fixed to the centre of the membrane and connected with the binding screw 2. The arm *a b c* is metallicly connected with the binding screw 1. The key *t* closes the circuit when the instrument is in use, and the electro-magnet E E is for the purpose of receiving communications.

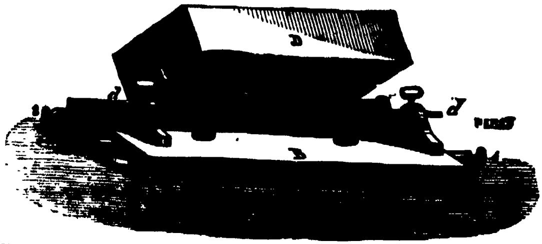

FIG. 2 is the receiving apparatus. B and D are resonant boxes, *g* is the coil through which the current passes magnetising the iron wire *d*, 3 and 4 are binding screws to which the line and return wire are attached, the circuit being closed by the key 1.

The first instrument he made was constructed of very homely materials. The bung of a beer-barrel was pierced [illegible]h with a conical hole, the smaller end was then [illegible]d by a membrane, the skin of a German sausage being used for this purpose; to this was fixed, with a drop of sealing-wax, a little strip of platinum joined up to one end of a small battery; a wire was adjusted near to, but not touching, the platinum strip; this wire led to the receiving instrument, and thence back to the other pole of the battery. On speaking into the conical orifice in the bung the membrane was thrown into vibration, and the attached metal strip coming into contact with the adjoining wire, momentarily completed the electric circuit. The vibrations of the membrane thus sent a corresponding series of intermittent currents into the receiver, which, in the first instance consisted simply of a knitting needle surrounded by a coil of wire, and placed on a violin to serve as a sound-board. Though Reis afterwards considerably improved upon his earlier instruments, the improvements do not seem generally known, and the arrangement just described is substantially that usually constructed and figured as Reis's telephone (see (Figs. 1 and 2.)

---

[1] *Phil. Trans.*, vol. 167, Pt. 1.

[2] Since this has been in type Dr. Haughton has read another paper before the Royal Society, in which he concludes, from purely geological evidence, that "the hypothesis of a shifting pole (even if permitted by mechanical considerations) is inadmissible to account for changes in geological climates." Therefore whether he agrees or not in the justice of my mechanical criticism, he seems to be of opinion that the wabbling of the earth will not give geologists much light as to the duration of geological

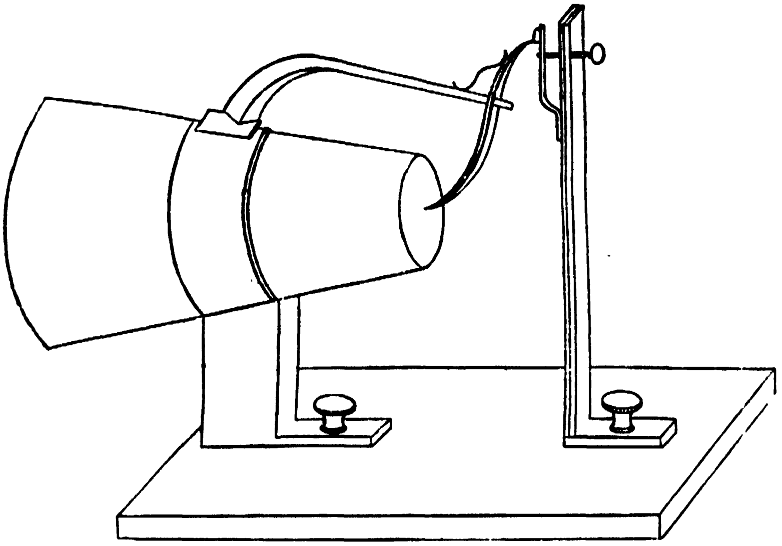

FIG. 3—Sketch of improved form of transmitter made by Reis in his telephonic experiment (1862).

In Dingler's *Polytechnisches Journal*, vol. 169 (1863), p. 29, is a report on Reis's improved telephone by Legat, inspector of telegraphs in Cassel, &c. This report was originally printed in the *Journal* of the East German Telegraph Company for 1862. Considerable modifications are here shown in both transmitter and receiver. The membrane is formed of a collodion film and is not loaded with any metal contact-breaker. A light S-shaped arm, supported a little above its centre, so as to move freely in a vertical plane, abuts at the lower end against the membrane, and at the [illegible] against the contact pin (Fig. 3). The circuit is com- through the cross-piece which supports the S-shaped ; the least outward motion of the membrane would thus break the contact, and in this way very feeble vibrations were able to be transmitted. The receiver consisted of, practically, a horse-shoe magnet fixed horizontally on a sound board; the movements of a light iron keeper, adjustible by a spring before the poles of the magnet, reproduced the original sounds (Fig. 4). Here it will be noticed a molar motion of the iron has replaced the molecular motion first employed. A much louder sound is thus

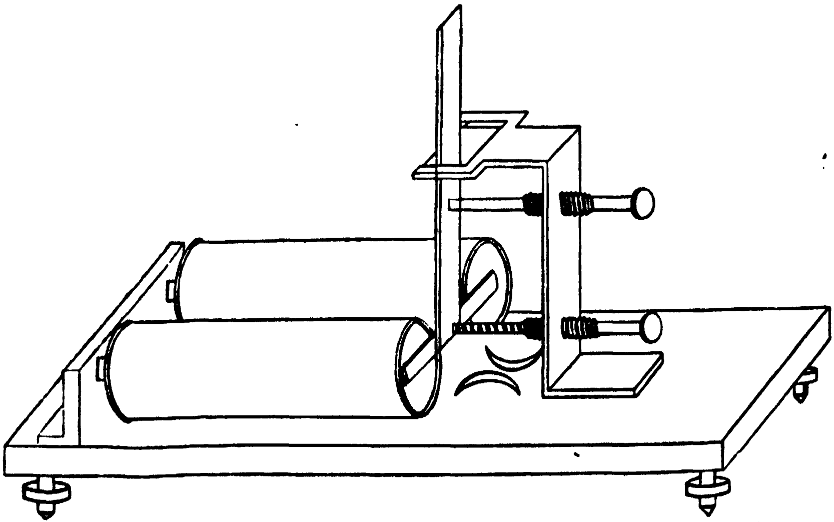

FIG. 4.—Sketch of improved form of receiver made by Reis in his telephonic experiments (1862).

obtained, and by bringing the iron keeper near to, or even into gentle contact with the magnet, every grade and rate of simple vibration could be reproduced, as the present writer is able to testify.

With this instrument Reis obtained better results and even transmitted imperfect articulation. Legat speaks of single words in reading and speaking being indistinctly heard; but any sudden modulation of the voice as in surprise, interrogation, &c., was clearly reproduced. Still more definite is the following statement, occurring in an article on Reis's improved telephone in No. 15 of Böttger's *Polytechnisches Notizblatt* (1863):—"The experimenters could even communicate to each other words, only such, however, as they had already heard frequently." In confirmation of this the present writer has received a letter from Dr. Messel, a name well known to chemists, who was a former pupil of Philip Reis and an eye-witness of his early experiments. Dr. Messel states—"There is not the shadow of a doubt about Reis having achieved imperfect articulation; I personally recollect this very distinctly and could find you many others who were witnesses of the same fact."[1]

As an interesting sequel to this historical note it should be mentioned that in 1865 Mr. S. Yeates, the skilful instrument maker of Dublin, introduced some modifications in one of Reis's instruments he had purchased, of the usual early form, which enabled him to obtain the distinct articulation of several words. The modifications were twofold: (1) the knitting needle receiver was replaced by an electro-magnet and movable keeper, as Reis had already done, though unknown to Mr. Yeates (see Fig. 5); and (2) a drop of very slightly acidulated water was placed between the contact pin and the metal disc on the membrane. The intermittent character of the current was thus abolished, and a very near approach made to the true principle of an articulating telephone, namely, the employment of a *continuous current* of varying strength. This instrument was shown in November, 1865, at a meeting of the Dublin Philosophical Society, and some members of that society who were then present have testified to their remembrance of the fact that several words were transmitted fairly well. It is to be regretted that at the time Mr. Yeates did not pursue the matter further, nor give a wider publication to the success he obtained.

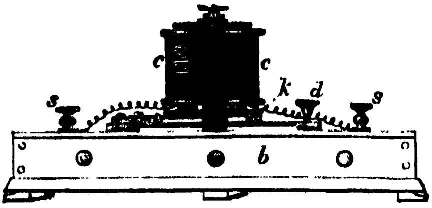

FIG. 5.—Yeates's receiver for Reis's telephone. Upon the sounding box *b* an electro-magnet *c c* is supported by the brass pillar seen behind. A light iron keeper *k* is fastened at one end by a steel spring to a wooden bridge, which can be raised or lowered by the screw *d*, so that the keeper can be brought almost into contact with the electro-magnet. The circuit is completed by the binding screws *s s*.

But between the best of the results obtained by Reis and others in the direction of articulation, and the splendid achievements of Prof. Graham Bell, there is unquestionably a very wide step. In the sensitive and beautiful instrument discovered by Prof. Bell, the voice of the speaker generates thrills of magneto-electricity, which, being strictly proportional to the sonorous vibrations, reproduces the voice and its expression in the receiver in a fairy-like far-away whisper. Nevertheless it must be borne in mind that it is unlikely the telephone of the future will employ the voice to generate the driving power, but only to modulate the flow of a current obtained by coarser means. It is in this direction that Reis worked, and though his method was faulty in the employment of an intermittent current, the same cannot be said of the arrangements adopted by Mr. Edison, of New Jersey. And inasmuch as Mr. Edison has already discovered and brought to a practical issue such remarkable additions to our knowledge as quadruplex telegraphy, the electro-motograph, and the phonograph, we have, in these achievements, the earnest of success to those excellent telephonic investigations wherein Mr. Edison has already won an enduring fame. W. F. BARRETT

P.S.—Since writing the foregoing article, the publication of which has been for some time delayed owing to the crowded state of the columns of NATURE, my attention has been drawn to a claim made by Mr. John Cammack, to be the first inventor of the electric telephone. From this it would appear that in the early part of 1860 Mr. Cammack made and exhibited an electric telephone, whilst a student in the Royal School of Medicine, Manchester. A photographic copy of the original drawing of the instrument has reached me, and so far as this goes it embraces not only the intermittent current used by Reis, but the principle of the continuous current of varying strength employed by Bell and Edison. In fact, if Mr. Cammack can furnish historical proof, the arrangement shown in his drawing, with its explanatory note, is identically the same as the method, long after independently invented and patented by Prof. Graham Bell.[1] W. F. B.

ACTION OF LIGHT ON A SELENIUM (GALVANIC) ELEMENT

IN the course of a series of experiments on the electrical behaviour of selenium, undertaken with a view to remove, if possible, the difficulties in the way of constructing constant resistances of this material, I have had occasion recently to investigate the effects of surface tension due to light.

I find that the action of light on crystalline selenium (annealed at 200° C.) is much more striking when the selenium forms one element of a galvanic couple than when it acts as a resistance.

The most convenient arrangement which I have found for observing this, is to make up a couple consisting of (1) a plate of selenium hanging suspended by means of a platinum wire, and (2) a strip of platinum foil, in distilled water. The potentials of the two poles are not very different, and any change in the electro-positiveness of the selenium is at once very apparent.

The first selenium-platinum element which I constructed behaved as follows:—

In the dark the element gave a steady electromotive force of about 0·1 volt, the selenium being *positive* to the platinum. On admitting daylight to the selenium plate it instantly became *electro-negative* to the platinum, showing an electromotive force of 0·05 volt in that direction. That is to say the selenium had become 0·15 volt more electro-negative by the action of the light than it was in the dark.

---

[1] My best thanks are due to Dr. Messel for much information concerning Reis and for a reference to his papers in the journals alluded to.

[1] Perhaps the word "claim" is too strong, as I observe Mr. Cammack speaks very modestly of the idea he so early sketched out. Such ideas are of course valueless in a practical sense, unless brought to the test of experiment, and this Mr. Cammack seems only partly to have done; this too is just where Prof. Bell succeeded; by his persistent experiments overcoming all obstacles and affording by the way a striking illustration that facts may after all upset the strongest *à priori* conclusions. In connection with this remark the following passage from the last edition of a well-known work on Mental Physiology (p. 632), is not without interest:—"Everyone who accepts as facts, merely on the evidence of his senses, or on the testimony of others who partake of his own beliefs, what Common Sense (with capitals) tells him to be much more probably the fiction of his own imagination—even though confirmed by the testimony of hundreds affected with the same epidemic delusion—must be regarded as the subject of a 'diluted insanity.'" Yet Bar[illegible]nchausen's trumpet has been outdone by the phonograph: the "fiction of imagination" by a fact "confirmed by the testimony of hundreds." However as these latter have "merely the evidence of their senses to offer," we presume they are all the victims of "a diluted insanity," if the reasoning of the eminent author be accepted.

"Mimicry" in Birds

IF Mr. Young will look at the fourth edition of Yarrell's "British Birds," he will find that the fact he mentions (*ante*, p. 486) has already attracted notice, for he will there read (vol. i. p. 616) :—

"In places near Thetford, where the ringed plover is common, skylarks often imitate the note of that bird, making it part of their own song." ALFRED NEWTON

Magdalene College, Cambridge, April 19

OUR starlings here, which are a numerous and accomplished colony, have acquired the following notes of other birds :—Curlew, red-shank, blackbird, thrush, magpie, swallow, swift, chaffinch, house sparrow, hedge sparrow. The most successful imitations are those of the curlew, red-shank (the note uttered by the latter on taking wing), and the swallow. I have several times this year been certain that I heard a swallow twittering on the house-top, and found that the note proceeded from a starling.

The jays also in this neighbourhood, which are very plentiful, are very able mimics; the note of the carrion crow is about their most successful effort. H. H. S.

Riding Mill-on-Tyne, April 22

The Westinghouse Brake

UNDER the heading, "Notes," in NATURE, vol. xvii. p. 140, there is a paragraph describing the automatic brake of the Westinghouse Brake Company, St. Stephen's Palace Chambers, Westminster, the latter part of which refers to a ball which performs certain functions under different circumstances. In a previous account in the *Times*, three balls are mentioned as being used in the experiment; it also states that several gentlemen were investigating the mathematical principles under which these functions fell. I have not seen any results of their work, neither is there any comment upon it in NATURE. I therefore take occasion to mention it, in order that if any account of it has passed me, I may be informed of it, or that, if no results have appeared, this may lead to the subject being investigated by some of the mathematical correspondents of your esteemed paper. G. O. K.

Sound and Density

SINCE velocity of sound does not vary with *density* (Balfour Stewart, Chap. IV., "Elementary Physics"), would you kindly state the answer that should be given to the question, *Why* does sound travel quicker in *water* and *wood* than in *air*, and what is the relation between *density* and *velocity of sound* in *water*, *wood*, *air?* J. CAMERON

The Academy, Montrose, April 18

[The velocity of sound depends on the ratio between the mass and the elasticity, and in air (to which Prof. Stewart refers) it does not vary with the density of the air if its temperature only remain constant. In this case the denser the air the greater the mass, but the greater the elasticity in the same proportion. The ratio between mass and elasticity is thus unaltered, and therefore the velocity remains under these conditions the same.—ED.]

OUR ASTRONOMICAL COLUMN

THE TRANSIT OF VENUS IN 1882.—In addition to independent calculations of the circumstances of this phenomenon, founded upon Le Verrier's tables of the sun and planet, to which reference has already been made in NATURE, we have to record the publication of two memoirs upon the same subject, the first by Herr Bruno Peter, who is attached to the Observatory at Leipsic, the second by Dr. Karl Friesach, of Graz, which has been received within the last week. As was to be expected where practised calculators are working upon the same data, the direct results from the tables are in very close accordance with those previously published; indeed the advantage of so many repetitions of such work is not very evident. The differences which the calculated times of the geocentric contacts exhibit are almost wholly due to the employment of different semi-diameters of sun and planet. Le Verrier suggested (*Annales*, vol. vi. p. 40) that for the present the values to be employed should be respectively 958″·424 and 8″·305 for the mean distance. Herr Peter has used 961″·21 and 8″·472, and Dr. Friesach, 960″·0 and 8″·305. Their results for Paris mean times of contacts and least distance of centres are subjoined :—

Transit of Venus, 1882, *December* 6.

ENCKE'S COMET IN 1878.—Observers in the southern hemisphere may be reminded that this comet is likely to be a pretty conspicuous telescopic object in their evening sky, in the first days of August. According to Dr. von Asten's latest researches on the motion of this comet, the period of revolution at the last perihelion passage was 1200·8 days, which, without taking any account of perturbations (not likely to be very material during the present revolution), would bring it again to perihelion on July 27. Mr. Tebbutt, of Windsor, N.S.W., has once found Encke's comet without assistance beyond his own calculations, but it will probably be Dr. von Asten's intention to furnish southern observers with a reliable ephemeris commencing with August next. Observations will not be practicable before the perihelion passage, the comet being too near to the sun's place.

THE "BERLINER ASTRONOMISCHES JAHRBUCH" AND THE MINOR PLANETS. The volume of this ephemeris for 1880 has just appeared under the joint editorship of Professors Förster and Tietjen. The general contents are similar to those of preceding volumes. The ephemeris of the moon is again transferred, with full acknowledgment from the *Nautical Almanac*, and a great amount of labour of computation is thereby saved, which is made to tell upon the specialty of the work, the preparation of ephemerides of the small planets as far as their orbits are sufficiently determined. The reader who may be in search of the elements of these bodies will find in this new volume of the *Berliner Jahrbuch* the most complete and reliable table yet in the hands of astronomers. It includes orbits of all the minor planets to No. 172, with the exception of No. 155, *Scylla*, for which the necessary materials for calculation are wanting; and while referring to *Scylla*, it may be remarked that the four observations on November 8, 9, 22, and 23, 1875, cannot be represented by an elliptical orbit, which raises a suspicion that those of November 8 and 9 may belong to one planet, and those of November 22 and 23 to another, not, so far, recognised in the list. On examining the table of elements it is seen that No. 153, *Hilda*, has by far the longest period, while No. 149, *Medusa*, is credited with the shortest, according to the calculations of Prof. Tietjen. The observations of *Medusa*, however, extend over a period of eight days only, but they appear very exact, and it has happened that from a similar short interval of accurate observation, very close approximation to the true elements of an elliptical orbit has been attained; we may especially note the case of the short-period comet of De Vico in 1844: from eight days' very precise observations, M. Faye deduced an orbit which, as was pointed out by Prof. Brunnow, was almost identical with the result of his own elaborate investigation of the elements from the whole extent of observation. It is unfortunate that *Hilda* has escaped observation at the last opposition, since of all the small planets it is most desirable to keep this one in view, from the fact of its orbit allowing of a very much closer approach to the planet Jupiter than is possible in the case of any other.

The best orbit is by Kuhnert, but it is probable that the want of observations in 1877-78 is not wholly attributable to errors of elements, but in a certain degree to the position of the planet at a considerable distance from the ecliptical belt of the sky for which charts of small stars are as yet published, and, in addition, to its faintness. *Medusa*, which appears to have a very small inclination, may possibly be recovered in the ensuing summer.

GEOGRAPHICAL NOTES

TASMANIA.—The prospects of Tasmania are reported to be improving, owing to the development of its mineral resources. Very large quantities of tin, as is well known, have been discovered at Mount Bischoff, and quite recently the vast tract of country to the north-west, which has always been looked upon as valueless, has been explored with more care, and though it is probably of little use for agricultural purposes it has been found to contain enormous quantities of iron and other minerals. Traces of gold have been met with in the beds of some of the rivers, and copper has also been found. In the dense forests which are common in this region specimens of the *Eucalyptus* have been seen which are said to be more than 300 feet in height. Further exploration is still being carried on with a view to the accurate determination of the capabilities of this part of Tasmania.

AFRICAN EXPLORATION.—Journalistic enterprise is again contributing to the exploration of Africa, and this time Paris is vying with London and New York. M. P. Soleillet, who has been equipped under the auspices of the *Moniteur Universel*, departs soon for a tour of exploration in Equatorial Africa, to follow in the footsteps of his fellow-journalist Stanley. The development of openings for French commerce is to form a prominent feature in the undertaking.

PARIS.—The Paris *Société de Géographie* has elected Baron de la Roncière Le Nourry its president for the ensuing year.

FRENCH GUAYANA.—Dr. Crevaux, who was sent out by the French government to explore the interior of French Guayana, has returned to Paris after completing one of the most arduous journeys in the annals of South American discovery. After having fulfilled his instructions to penetrate to the Tumuc-Humac range, he determined to make the passage of these mountains, and descend into the valley of the Amazon, an attempt which has several times been tried in vain during the past three centuries. Although deserted by all his attendants, with the exception of a negro, he succeeded, after overcoming numerous obstacles, and battling with famine during a march of sixteen days across an uninhabited tract, in reaching the head waters of the Yary, from whence a canoe-voyage brought him to the Amazon. Of the 500 leagues traversed in this journey, 225 were hitherto completely unknown.

SURVEY OF NEW YORK.—The Second Annual Report of the State Geographical and Topographical Survey of New York, in charge of Mr. James T. Gardner, gives an account of the labours of the commission during the year. The principal work of the year has been the precise determination by primary triangulation of points in eleven counties, embracing an area of about 3,000 square miles; 167 points were located in an area of 1,700 miles in seven counties alone; the average has been one to every ten square miles. Fifty-one monuments have been placed in defining the boundaries of counties, this being a very important part of the work of the survey. The report is accompanied by several maps showing the progress of the work, the position of the stations, &c.

BIOLOGICAL NOTES

A NEW FRUIT.—Mr. Hollister has introduced from Japan to San Francisco a fruit, which is said in its native country to have as many varieties as are grown in this country of our apple, and the sweetness of the fruit is more or less retained by all of them. It is known as the Japanese Persimmon and, according to Mr. Hollister, is the most beautiful of all the fruits he had ever seen and the most delicious to the taste—four of the fruits which ripened with him weighed three quarters of a pound each, they were of a rich yellow colour, and looked like balls of wax; these were pronounced equal to a good pear or peach. The tree is a highly ornamental one, a prolific bearer, and as hardy as a pear. Its fruit season is from October to March. It seems quite adapted to the soil and climate of California. The grafted trees bear in four years. The seedlings require double that time, and are not reliable (*Proceedings*, Acad. of Science, California, in *American Naturalist* for March, 1878). This is the well-known and beautiful fruit of *Diospyros kaki*, Linn., fil., a near ally of the Persimmon of the Southern United States of America. Mr. Hiern tells us in his Monograph of the Ebenaceæ that the Chinese preserve this fruit with sugar, and that it has for a long time been in cultivation with them and the Japanese. The fruit has a thin skin, with a sweet orange-scarlet coloured flesh, with six or eight dark smooth seeds. It was beautifully figured in the *Gardeners' Chronicle* for 1872.

FOSSIL INSECTS.—Messrs. S. H. Scudder, of Cambridge, and F. C. Bowditch, of Boston, attached to Hayden's United States Geological and Geographical Survey, spent two months in Colorado, Wyoming, and Utah, in explorations for fossil insects and in collecting recent coleoptera and orthoptera, especially in the higher regions. They made large collections of recent insects at different points along the railways from Pueblo to Cheyenne, and from Cheyenne to Salt Lake, as well as at Lakin (Kansas), Garland and Georgetown (Colorado), and in various parts of the South Park and surrounding region. Ten days were spent at Green River and vicinity in examining the tertiary strata for fossil insects, with poor results. The tertiary beds of the South Park yielded only a single determinable insect; but near Florissant the tertiary basin described by Mr. Peale in one of the annual reports of the Survey was found to be exceedingly rich in insects and plants. In company with Rev. Mr. Lakes, of Golden, Mr. Scudder spent several days in a careful survey of this basin, and estimates the insect-bearing shales to have an extent at least fifty times as great as those of the famous locality at Œningen in Southern Bavaria. From six to seven thousand insects and two or three thousand plants have already been received from Florissant, the specimens from this locality being remarkable for their beauty. There is every reason to believe that the tertiary strata of the Rocky Mountain region are richer in remains of fossil insects than any other country in the world, and that within a few months the material at hand for the elaboration of the work on the fossil insects of the American tertiaries which Mr. Scudder has in preparation, will be much larger than was ever before subject to the investigation of a single naturalist. Mr. Scudder has in all now more than 12,000 specimens of fossil insects.

THE CLIMBING OF THE VIRGINIA CREEPER.—Mr. B. D. Halsted has studied the mechanism of climbing in the Japanese Ampelopsis, and finds that the clinging discs terminate tendrils which are homologous with main stems. While approaching a support, these discs flatten themselves on the inner side. The surface of the disc is papillose, and excretes a sticky substance; and the irregular contraction of the tendril draws the vine to its support (*Proc.* Boston Soc. Nat. Hist., January, 1878).

about the same course as that for pure water, except that the maximum of density was reached, not at 4°, as in the case of pure water, but under 3°, as is the case with salt substances.

RECENT observations by M. Ebermayer demonstrate (1) that the air in a large forest is in summer nearly twice as rich in carbonic acid as free open air; (2) that forest ground in summer contains much less CO$_2$ than unwooded ground (the CO$_2$ formed by slow decomposition of humus in the close forest seems mostly to pass into the air, and is probably utilised by the leaves for assimilation); (3) that, with rise of temperature, the increase of CO$_2$ in arable ground is very much greater than in forest ground; and (4) that the spread and motion CO$_2$ in the ground seems to take place very slowly, for in two places quite near together the amount of CO$_2$ may be very different. Among other bearings of these facts, the ground covering of a forest can have no important influence on the amount of CO$_2$ and lime in spring water, and unwooded ground may have a greater action in this respect. Again, animals living underground, *e.g.* foxes, naturally prefer the ground air of the forest, with its little CO$_2$, to to the ground air of the open field, which has much more.

THE influence of concentration of liquids on their electromotive force has lately been investigated by M. Moser (*Monatsb. der Berliner Acad. der Wiss.*) who connected two glasses of differently concentrated solutions of the same salt by a siphon, and completed the circuit by wires with electrodes, which were always of the same metal. In all such cases a current arises, passing in the liquid from the dilute to the more concentrated solution. M. Moser used zinc sulphate, nitrate, chloride, and acetate, copper sulphate and nitrate, iron chloride, silver acetate and nitrate, and other salts. The highest electromotive force was ⅛ Daniell, and was got with very dilute and concentrated zinc chloride solution. The various effects are arranged in tension-series. By the currents referred to, metal is dissolved in the dilute solution, separated out in the concentrated one. The equivalent of the work done by the current, M. Moser considers, is the work of attraction force between the salt and the water. The current is to be regarded as a reaction current against passage of the ions, as the polarisation current is the reaction current against the decomposition current.

THE subject of acoustic repulsion continues to be studied by M. Dvorak (*Wied. Ann.*, No. 3). Among other things he constructs an acoustic reaction wheel and an acoustic torsion balance. The former consists of four light paper or glass resonators placed tangentially at the four ends of two thin cross-bars of wood, pivoted at their intersecting point by means of a glass cap. The mouths of the resonators are all in the same relative position. The wheel is placed before the open end of a tuning-fork resonator, and enters into rotation when the fork is sounded. In another case the sound from the large resonator is transmitted through a conical tube beyond whose thin end is a wheel with square pieces at the end of the cross-arms. In the acoustic torsion balance a wooden bar furnished with a resonator is hung by a wire (as in Coulomb's balance) within a case, which has on the resonator side an opening for admission of sound. By repulsion of the resonator the strength of tones of the same number of vibrations may be compared.

LECTURING at the Sorbonne lately on atmospheric electricity, M. Mascart sought to reproduce the phenomena of thunderstorms. The dull explosions of thunder and the fulgurations in the heart of clouds preceding fulminant discharges, as also the latter, were imitated by means of a powerful Holtz machine, charging batteries, and condensers suitably arranged. The singular movements of thunder-clouds, which, obeying electric attractions and repulsions, are often observed to move in the atmospheric ocean in counter-currents, were illustrated with the aid of a balloon of hydrogen gas, to which was suspended a piece of metallic wire. The weight of the wire was such that the small aerostat, rendered slightly heavier than the displaced air, would descend; but when it was electrified, it rose again, as if freed from its burden. M. Mascart did not attempt an explanation of this curious phenomenon, which has not been repeated since the time of van Marum.

IN a recently-published report by M. Kellner to the Naturforscher Versammlung at Munich, he describes experiments made along with some others on an eleven-year old Wallachian horse of 434 kilo. weight, with regard to the relation of work done and decomposition of albumen. In five successive periods of thirteen to fourteen days the animal was fed with 5 k. meadow-hay, 5 k. oats, and 1·5 k. chopped wheat straw, and did work to the extent of 500,000, 1,000,000, 1,500,000, 1,000,000, and 500,000 kilogrammetres in the five periods respectively. In periods I. and V. the work done was the same, in II. and IV. doubled, and in III. tripled; in II. and III. the course was doubled and tripled, and in IV. the weight doubled. Of the dry substance of the fodder were digested in period I. 56·53 per cent., II. 56·45 per cent., III. 56·49 per cent., IV. 54·01 per cent., V. 53·07 per cent. The horse's weight varied as follows:—I. 534·1, II. 529·1, III. 522·3, IV. 508·8, V. 518 kilo. The excretion of nitrogen was on an average of the last six to nine days of each experimental series, I. 98·81 k., II. 109·16, III. 119·82, IV. 107·53, V. 101·88. These numbers show strikingly, in opposition to Voit's and Pettenkofer's results, that with increase of work done, is associated a not inconsiderable increase of decomposition of albumen.

THE additions to the Zoological Society's Gardens during the past week include an Indian Leopard (*Felis pardus*) from India, presented by Major Tubbs; a Red Deer (*Cervus elaphus*), a Common Fox (*Canis vulpes*), European, presented by Mr. Carroll W. Ansdell; two Spotted Ichneumons (*Herpestes auropunctatus*) from Nepal, presented by Mr. J. McIntosh; a Suricate (*Suricata zenik*) from South Africa, presented by Mr. Percy Howard; an Azara's Fox (*Canis azaræ*) from Brazil, presented by Dr. A. Stradling; a Stanley Crane (*Tetrapteryx paradisea*) from South Africa, presented by Capt. A. F. Lendy; a Leadbeater's Cockatoo (*Cacatua leadbeateri*) from Australia, presented by Mr. W. Ruston; a Collared Fruit Bat (*Cynonycteris collaris*), four Common Foxes (*Canis vulpes*), born in the Gardens.

THE DETERIORATION OF OIL PAINTINGS[1]

II.

IF we compare the pictures of the Italian and Dutch schools of the fifteenth, sixteenth, and seventeenth centuries, with those of the French and English schools of the last hundred years, we are struck by the great difference in the nature of their diseases. We may divide those diseases into *constitutional* ones—that is to say, such as are based on the method and the material used for painting, and into those produced by external influences.

The Dutch pictures of the fifteenth, sixteenth, and seventeenth centuries, and the Italian pictures of the fifteenth and sixteenth centuries, seem to me perfectly free from constitutional diseases. It is only in the seventeenth century that the Italian pictures show a special constitutional alteration, caused by the practice of the Bologna school.

The pictures of the last hundred years of the French school, of a part of the English school, and some painters of other schools, have been attacked by a constitutional disease perfectly defined and characteristic of this period.

Among external influences injurious to oil painting, we have to consider dampness, heat, bad air, dust, smoke, mechanical injuries, and last, not least, the destructive or "altering" hand of the picture-restorer.

Pettenkofer's scientific researches first clearly defined th influence of humidity on oil paintings, showing that it produc a discontinuity of the molecules of the vehicle and the resin substances. As glass, when pulverised and thereby mixed air, loses its transparency, and water, when mixed wit becomes of a milky aspect, so the oily and resinous substances contained in paintings will become dim as soon as air penetrates between their particles. The picture thus assumes a greyish, dim appearance, and the pigments seem to have been fading. That this is not really the case has been proved by the influence of a process invented by Pettenkofer, which he calls regeneration. In a flat box the picture is exposed to air impregnated with alcohol. Of this latter the resinous elements of the picture absorb a certain quantity, swell and fill up the interstices between the separated particles so as to reunite them into an optically homogeneous transparent substance.

---

[1] Paper read at the Royal Institution, Friday, March 1, by R. I M.D, M.R.C S., M.R.I. Continued from p. 495.

The alcohol does not affect in the same way the hardened oil. If the interstices between its particles are not filled up by the swelling resin, it becomes necessary to introduce a new substance into the picture, and this is called nourishing a picture.

Pettenkofer has the great merit of having clearly proved that the nourishing of a picture with oils, as the custom was formerly, and still is to some degree, is a very objectionable proceeding, as it has the effect of darkening the colours for ever. He recommends, instead of oil, balsam of copaiva, which has become since an invaluable means for preserving and restoring oil paintings, and will be more and more extensively used.

I have frequently applied Pettenkofer's method, and with very beneficial effect; but whenever I mentioned it to professional picture-restorers, here as well as on the Continent, I always found them to reject it, either *à priori*, or after experiments incorrectly made.

In Munich, it seems, the pictures of all periods and of all schools have had to suffer under local influences and through the changes in the humidity of the air. This accounts for Pettenkofer having principally described this, so to say, endemical disease. In other galleries this affection does not appear so frequently, and Pettenkofer's method, therefore, will not find everywhere the same extensive application as at Munich. I think, however, that with some modifications it may be employed against some other alterations. I have, for instance, found it efficacious with paintings which had been injured by exposure to great heat. I shall show you a small picture which had been hanging for a long time so near a gas flame that it was almost completely scaling off, and so entirely faded that it scarcely looked like an oil painting at all. In that state it was exposed to alcoholised air, then nourished with balsam, and its back slightly varnished; and the scales starting from the canvas were refixed by pressure. And now it appears fresh in colour, firm in substance, and perfectly smooth on its surface. The old, cracked varnish, melted together by the alcohol, looks as if fresh laid on.

Humidity sometimes favours the development of fungus. The round, black, small spots which pass through the canvas and the painting of these two pictures are produced by the same little plant which Prof. Tyndall showed you when he spoke on the highly interesting subject of spontaneous generation.

Oil and water, so injurious to oil paintings, enter both into the material used for lining. Anxious to exclude these sources of danger, and to simplify the whole process, I have endeavoured to replace it by a new method which I shall submit to you this evening.

How paintings may be disfigured by restorers you see in this picture, which was renovated with oil colours according to the practice only abandoned about thirty years ago, when it was advantageously replaced by the use of varnish colours.

The amount of external injury oil paintings sometimes endure and stand is perfectly amazing. Pictures in the course of centuries, during the destructive fury of wars and revolutions, may have been torn out of their frames, rescued from below the ruins of burned monasteries, may subsequently have passed from one *bric-à-brac* shop to another, where they have been piled up, to be pulled about at each new inspection, and literally trodden under foot, whereby they have finally been reduced to a state of colourless, greyish, or black rags. Still such pictures may not unfrequently be awakened, as it were, to new life, to their original brilliancy of colour, if, with all necessary care, their injured limbs are put together again, their wounds are healed, and fresh nourishment, air, and thorough cleansing, are administered to their lacerated bodies.

A sound constitution is, of course, a necessary condition for obtaining any such result, without it we can only obtain a partial cure. We see this with reference to the Bolognal school of the seventeenth century. The pictures which you see here are instances of this. From the state of rags to which they were reduced they have passed, by appropriate treatment, into the state of firm, even, well-conditioned, and clean pictures. The constitutional alteration characteristic of their time and school, however, could not be cured. You will, therefore, perceive that the contrast is too great between light and shade, that the half tones are too weak and that the glazings spread on dark ground, which certainly existed formerly, have been destroyed by the growing of bolus and umber of the priming. That this is not the fault of the method of restoration is clearly proved by the state in which you will find all the pictures of this school, even those best preserved in the best galleries of all countries.

The constitutional diseases of pictures belonging to the French and to the English school of the last hundred years are of still more serious nature, and much more difficult to cure. Many of them, though they were never exposed to any injury whatever, nor are likely ever to be so in our present state of civilisation, cannot be guarded from premature decay in spite of all possible care with which they are kept.

The principal symptoms of their bad constitution are:—

1. Darkening of the opaque bright colours.
2. Fading of the transparent brilliant colours.
3. Darkening, and above all, cracking of the transparent dark colours.

The best opportunity to study these several appearances is given us in the Museum of the Louvre, which contains a great number of such pictures in the section occupied by the French school. I have paid particular attention to the cracks in these pictures, as I find that in shape, in size, in position, as well as in relation to the various colours, they differ distinctly from the cracks in older pictures and in those of other schools. This, of course, is of importance, not only for the explanation of the reasons which produced them, but as a symptom which, in a given case, might determine the diagnosis, whether a picture be an original or only a copy. The special characteristics of these cracks are the following:—

They are all but exclusively found in the thickly laid on transparent dark colours, and they are the deeper and the more gaping in proportion to the thickness of the layer of the colour and the extent of the dark surface. The chief cracks run parallel to the outlines of surfaces painted with bright opaque colours, such, for instance, as are used for the flesh tints, and which are more or less thickly laid on. But there is generally a slight distance between the bright colours and the cracks.

Lateral branches of these cracks pass into the white, but they do not gape, provided the white colours had been laid on directly upon the priming, and not upon a layer of dark transparent and not sufficiently dried colour.

This examination of the cracks of pictures has sometimes afforded me a peculiar insight into the practice used for the picture. In the well-known picture, for instance, by Guéricault, of "The Wreck of the *Medusa*," in the Gallery of the Louvre, the cracks follow exactly the outlines of the bright flesh-tints. The arm of one of the dead bodies hanging in the water is so covered by planks and water that nothing of the forearm is to be seen. It is, however, very easy to prove that originally that arm was painted in all its length, for the cracks do not only follow the outline of the visible upper arm, but also the no longer visible forearm, and all the five fingers. This proves that the fore part of the arm and the hand were originally painted in flesh-tints before they were covered over by the planks, and the water painted afterwards. In Ingres' portrait of Cherubini, the face of the latter is beautifully preserved, while that of the Muse, as well as her drapery, is covered with cracks. In the depth of the cracks of the white drapery an intense blue tint is to be seen. Mr. Henry Lehmann, of Paris, the favourite pupil of Ingres, who knows the history of this picture as an eye-witness, and whom I consulted about this very striking appearance, gave me the following information:—Ingres painted the head of Cherubini in Paris, and then took it with him to Rome. There it was pieced into a new canvas and lined. Then the Muse was painted, and before the colours were perfectly dry, another model was chosen, and a new Muse painted over the old one. The colour of the drapery was likewise altered, and this explains the cracks in the white colour, and explains also why the blue appears in the depth of the cracks of the drapery.

Among the English artists of the last hundred years, some have painted with the same material and by the same process as their French contemporaries, and consequently with the same unfortunate results. Others avoided these by using the same material with more precautions. Others, again, and among them Sir Joshua Reynolds, have in their different works followed various practices, and consequently had varied results. Thus, some of Sir Joshua's pictures have kept perfectly sound. Others are cracked in the characteristic way just mentioned. Others, again, are cracked in an absolutely irregular way. We can easily form an idea of it if we read in his "Diary Notes," for instance, the way in which he painted the portrait of Miss Kirkman, which he began with whiting and gum tragacanth, then covered it successively with wax, then white of eggs, and then varnished it.

The study of the alterations already fully developed in pictures painted within the last hundred years only, and their comparison with the works of the old masters, would suggest the following rules for the process of painting:—

1. The oil should in all colours be reduced to a minimum, and under no form should more of it than absolutely necessary be introduced into a picture.

2. All transparent colours which dry very slowly should be ground, not with oil at all, but with a resinous vehicle.

3. No colour should be put on any part of a picture which is not yet perfectly dry; and, above all, never a quick-drying colour upon a slow-drying one, which is not yet perfectly dry.

4. White and other quick-drying opaque colours may be put on thickly. On the contrary, transparent and slow-drying colours should always be put on in *thin layers*.

If the effect of a thick *layer of these latter* is required, it must be produced by laying one thin layer over another, taking care to have one *completely* dry before the next is laid on. If transparent colours are mixed with sufficient quantity of white-lead, they may be treated like opaque ones.

We come now to the last layer of the picture, to that one which is spread over its surface in order to equalise optical irregularities, and to protect it at the same time from the air. I mean the varnish.

The varnish may crack or get dim; then it should be treated with Pettenkofer's method; but it may become dark yellow, brown and dirty, and so hide the picture that it becomes necessary to take it off and to replace it by a thin layer of new varnish. It is here that picture-restorers, or we may say picture-cleaners, display their beneficial skill, and also their very destructive activity.

If a picture is throughout painted in oil, if its substance has remained sound and even, and varnished with an easily soluble mastich or dammar varnish, then there will be neither difficulty nor danger in removing the varnish. This can, in such a case, be done either by a dry process, that is, by rubbing the surface with the tips of the fingers, and thus reducing the varnish by degrees to a fine dust, or by dissolving the varnish by application of liquids, which, when brought only for a short time into contact with the oil painting, will not endanger it. We have, however, seen that the works of the old masters are not painted with oil colours like those used by modern painters, but, on the contrary, that certain pigments, and especially the transparent colours used for glazing, were ground only with resinous substances. These latter have, in the course of time, been so thoroughly united with the layer of varnish spread over the surface of the picture, that there no longer exists any decided limit between the picture and the varnish. It is in such pictures that a great amount of experience, and knowledge of the process used for the picture, as well as precaution, are required in order to take away from the varnish as much only as is indispensable, and without interfering with the picture itself. Numberless works of art have been irreparably injured by restorers, who, in their eagerness to remove dirt and varnish, attacked the painting itself. They then destroyed just that last finishing touch of the painting, without which it is no longer a masterpiece.

The difficulty and danger are much greater in cleaning those pictures which have not been varnished with the ordinary easily-dissolved mastich or dammar varnish, but have been painted over with oil, oil-varnish, or oleo-resinous varnish. It seems incredible that these substances should ever be used for such purposes; it is, however, a fact that there are still people who fancy that it will contribute to the good preservation of their pictures to brush from time to time a little of those liquids over their surface. They recognise too late that the varnish becomes more and more dark, of a brownish colour, and opaque. If varnish has afterwards to be removed, then we meet with great difficulty, that this can be done only with substances which would just as easily dissolve the whole picture as the hardened layers spread over it.

This shows what can be the value of those universal remedies which from time to time appear, and are praised for the innocuous way in which pictures by their means may be cleaned.

There is at this moment a great discussion going on in Italy about Luporini's method. Luporini is a painter and picture-restorer in Pisa, who believes himself to have invented a new means of cleaning pictures without any danger. Some months ago, in Florence, I examined a large number of pictures cleaned by him. Those of the Gallery of St. Donato, belonging to Prince Demidoff, mostly Flemish and Dutch landscapes, are cleaned very well and without any injury to the painting. On the contrary, the St. John, by Andrea del Sarto, one of the finest pictures of the Palazzo Pitti, I found very much altered by the restoration of Luporini. I had studied that picture very closely the year before, and should now sooner believe it to be a modern copy than the cleaned original. It has lost all softness of outline and the characteristic expression of the face. The change in the flesh tints can scarcely be explained otherwise but by an entire removal of the glazing.

I think it is taking a heavy responsibility to allow a new experiment to be tried upon such an invaluable work of art. Even private persons, who are fortunate enough to be in possession of such treasures, ought to feel responsible for the good preservation of masterpieces, which are, it is true, their material property, but which intellectually belong to the whole civilised world of the present and of the future.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Messrs. Mackren, Robbs, and Hichens, have been appointed to Scholarships in Natural Science at Gonville and Caius College.

EDINBURGH.—At the Graduation Ceremonial on Tuesday the degree of Doctor of Science in the Department of Mental Science, was conferred on Jacob Gould Schurman, B.A.; in the Department of Mathematics on Alexander Macfarlane, M.A., B.Sc.; in the Department of Chemistry on William Inglis Clark, B.Sc. The degree of Bachelor of Science was conferred on William Thomson in the Department of the Mathematical Sciences; on John Adrian Blaikie and James Johnstone Dobbie in the Department of the Physical Experimental Sciences; on William A. Haswell in the Department of the Natural Sciences; on James Alfred Ewing and John Gray in the Department of Engineering; and on John Brown, M.D., John Berry Haycraft, M.B., C.M., and John Trehame, M.B., C.M., in the Department of Public Health. The Hope Prize Scholarship in Chemistry was awarded to Mr. Lewis Johnstone, and the Falconer Memorial Fellowship for the encouragement of the study of Palæontology and Geology, of the annual value of 100*l*., tenable for two years, and conditionally for four years, was awarded to R. A. Lundie, M.A., B.Sc.

BALTIMORE.—We recently referred to the system of fellowships at the Johns Hopkins University, Baltimore. From a statement on the subject which has come to hand, we learn that twenty fellowships, each yielding 500 dols. a year, are annually open in the University. They are awarded by the trustees on the nomination of the Faculty, as nearly on the first of June as may be found practicable. Candidates are invited from any part of the country. The object of this foundation is to give to a few scholars of promise the opportunity to prosecute further studies, under favourable circumstances, and likewise to open a career for those who propose to follow scientific and literary callings. The University expects to be benefited by the presence and influence of the Fellows, and by their occasional services; from among the number it hopes to secure from time to time some of its teachers. Three of the twenty fellowships are allotted this year to each of the five departments, Greek, mathematics, chemistry, physics, and biology; and the remaining five will be allotted either in these departments or in others, at the discretion of the Faculty. Appointments are made by a careful consideration of all the evidence submitted to the Faculty. Every candidate in presenting his name is expected to address a letter to the president indicating the course of his previous reading and study, and his general purposes with reference to future work. It is desirable for him to present in printing or manuscript an essay or thesis which may have been written either for this occasion or for any other purpose. If he has been engaged in any scientific or literary research he should indicate its character, and generally give evidence as to his previous career and *bonâ fide*s. The holders of the fellowships are required to reside in Baltimore during the entire academic session, and they are not permitted to engage in teaching, out of the walls of the University, unless for exceptional reasons in other colleges which may ask for some temporary service. They are expected to devote all their time to study under the guidance of one of the professors, or if there be no professor in the chosen department, under the general approbation of the Faculty. Toward the close of the Academic year a report of his work is expected from each Fellow. As opportunities offer, the Fellows are encouraged to prepare and read lectures or essays on subjects to which they have given special attention. They are also required to render occasional services as examiners or as assistants in the laboratories; but those services are not burdensome, unless they are compensated by additional stipends. Those who become distinguished by their attainments may be assured of the constant encouragement of the Faculty. With all these precautions there seems little chance of the Johns Hopkins University being eaten up by idle Fellows.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 11.—"The Acceleration of Oxidation caused by the Least Refrangible End of the Spectrum," by Capt. Abney, R.E., F.R.S.

In a paper contributed to the *Philosophical Magazine* in January last, the author expressed an opinion that Chastaing's idea regarding an acceleration of oxidation being caused by red light might prove true in regard to the oxidation of the photographic image, and elsewhere[1] that Becquerel's coloured spectra might be explained on the same principles, and this he finds to be true as regards oxidation of the photographic image.

A silver bromide film was exposed to diffused light. It was then submitted to the action of the solar spectrum, whilst immersed in a solution of potassium permanganate, hydroxyl, potassium bichromate, or nitric acid, or in ozone. When the strength of these was correct, a reversed image of the least refrangible end of the spectrum was obtained, an increase in oxidation taking place where the red rays acted, the reversal commencing somewhere near D, and extending into the ultra-red.

The accelerating effect of the red rays is most marked when the solutions are weak; but there is a limit to the dilution caused by the fact that in the films employed the silver salt is sensitive as far as the wave length 10,000, and there must be sufficient strength to oxidise the invisible image as it is formed, besides gradually destroying the effect of the preliminary exposure. With silver iodide, as there is no reduction by the red rays, the reversed action is much more readily obtained.

A reversed image of the least refrangible end of the spectrum can thus be produced by using solutions of a certain strength, whilst if made more dilute an unreversed image is obtained. This throws a light on Draper's photographs of this region of the spectrum.

Geological Society, March 6.—Henry Clifton Sorby, F.R.S., president, in the chair.—Henry Edward Richard Bright, George James Cotton Broom, William James Farrer, George Scamell, and Joseph Fletcher White were elected Fellows of the Society.—The following communications were read:—On the geology of Gibraltar, by Prof. A. C. Ramsay, F.R.S., and James Geikie, F.R.S. In this paper the authors, after giving some account of the physical features of Gibraltar, described in detail the various rock-masses of which the peninsula is composed. The chief rock is a pale grey, bedded limestone, overlain by shales containing beds and bands of grit, mudstone, and limestone. Fossils are very rarely met with in the limestone, and have never as yet been found in the shales. The only recognisable fossil they obtained from the limestone was a *Rhynchonella*, which Messrs. Etheridge and Davidson think is most likely *Rh. concinna*. This would make the beds of Jurassic age. The limestone forms the great eastern escarpment, and dips west under the shales, which form the lower slopes upon which the town is built. The dips vary from 12° or 20° up to vertical. The connection of these strata with the rocks of the adjoining districts in Spain and the opposite coast of Africa was traced, and it was shown that the Gibraltar limestone reappears in Ape's Hill in Barbary, while the overlying shales and the sandstones of Queen of Spain's Chair form all the ground to the west of Ape's Hill up to Cape Spartel. The Jurassic strata of Gibraltar are overlain by various superficial accumulations, the oldest of which is a great mass of limestone agglomerate, which is unfossiliferous, and shows as a rule no trace of stratification. It is made up of angular blocks of limestone of all shapes and sizes, and rests upon an uneven surface of limestone: it also covers wide areas underneath which only shales are present. It is excessively denuded, being worn into ravines and gullies, and presents generally a highly honeycombed surface. Terraces of marine erosion have also been excavated in it. It is not now accreting, and could not have been formed under present conditions of climate and surface. The authors gave at length their reasons for believing it to have been the result of a severe climate. The blocks were wedged out by the action of frost, and the heaps of angular *débris* thus formed were saturated by water derived from melting snows, and so were caused to flow *en masse* down the mountain slopes and over the gently inclined ground at their base. The caves and fissures of Gibraltar were then described. It was shown that the true bone-breccias were confined to these. Many of these fossiliferous breccias are of later date than the great agglomerate, since they are met with in fissures and caves that intersect the limestone and limestone agglomerate alike. When the mammalia tenanted Gibraltar, Africa and Europe were united, and the climate was genial. All round the rock occur platforms, ledges, and plateaus, which are evidently the work of the sea. These erosion-terraces are covered in many places with calcareous sandstones containing recent species of Mediterranean shells. Such marine deposits occur up to a height of 700 feet. The movement of depression was interrupted by pauses of longer or shorter duration, and the climatic conditions were probably much the same as at present. After the rock had been re-elevated, the subaërial forces modified the surface of the marine sands that covered the limestone platforms, so that they came to form long sand slopes. The land at this period was of greater extent than it is now, and some grounds exist for believing Europe to have been again united to Africa, for mammalian remains occur here and there in the deposits that overlie the limestone platforms. These relics, however, it is just possible may be derivative. The climate was probably still genial like the present. Overlying the marine and subaërial deposits just referred to occurs an upper and younger accumulation of massive unfossiliferous limestone agglomerate. This deposit the authors believe to owe its origin to severe climatic conditions. After the marine deposits that cloak so much of the eastern side of the rock had been weathered into subaërial sand-slopes, large blocks were detached from the cliffs and steep slopes, and these dropped down upon the sands and were soon drifted over. By and by the blocks fell in such quantities that the sand-slopes in many places were completely buried under a talus of limestone *débris*. This was subsequently consolidated by infiltration into a solid agglomerate, in the same way as the underlying sands were hardened into sandstone. These sandstones contain a few blocks of limestone only in their upper portions. In their horizontally-bedded and lower-lyin portions no limestone blocks occur. This later agglomerat bears every stamp of great antiquity, and could not have bee formed under present geographical and climatic conditions. The surface is honeycombed and worn, just like that of the solid limestone and the older limestone agglomerate. Since its accumulation the climate has greatly changed, the present being characterised by the absence of frost. In concluding, the authors discussed at length the cause of the cold conditions that gav rise to the great limestone agglomerates, and argued that thi cause could not have been *elevation of the land*. They als pointed out that a *submergence of the Sahara* would be equally incompetent to bring about the desiderated climatic conditions, and that even a former much greater elevation of the land, combined with the appearance of a Sahara sea, would fail to supply us with the severe winter climate that was necessary to produce the great agglomerates. They thought that the most probable explanation of the phenomena described is that the cold conditions referred to were contemporaneous with that general refrigeration of climate which took place over so vast an area in our hemisphere during pleistocene times. The limestone agglomerates they look upon as the equivalents of those glacial deposits that occur so plentifully in our own and other countries, and the bone breccias, which are intermediate in date between the lower and upper limestone agglomerates, are paralleled by the interglacial beds of the British Islands, Sweden, Switzerland,

&c.—Notes on the geology of Japan, by J. G. H. Godfrey, F.G.S.

Physical Society, March 16.—Prof. W. G. Adams, president, in the chair.—A special general meeting was held for the election, as an *ex officio* honorary member of the Society, of the President of the Physical Society of Paris.—The following candidates were then elected Members of the Society:—J. S. Bergheim, W. M. Hicks, M.A., Dr. J. Hopkinson, M.A., D.Sc., Miss E. Prance, and T. Wills.—The Secretary read a paper by Mr. W. J. Millar, C.E. on the transmission of vocal and other sounds by wires. The author was led, mainly by a consideration of the manner in which sounds are conveyed through walls and partitions, to make an extensive series of experiments on this subject, from which he concludes that conversation can be carried on at considerable distances by simply employing stretched wires provided with suitable vibrating discs. In one experiment two copper wires were attached to points on a telegraph wire 150 yards apart, and breathing, singing, &c., were distinctly audible; by stretched wires extending through a house and provided with mouth- and ear-pieces in the several rooms, conversation could be carried on without difficulty. The materials employed for terminals were very varied, and the vibrating disc, whether metal, wood, or india-rubber, &c., was generally formed as a drum-head, the wire being fastened at its centre. The volume of sound appears to be greater with a heavy wire, but in all cases it requires to be stretched.—The President referred to the experiments of Wheatstone on the conduction of sound by vibrating bodies, especially long wooden rods. He mentioned that in 1856 a performance was given at the Polytechnic at which numerous experiments connected with such conduction were exhibited. Some years ago M. Cornu, in conjunction with M. Mercadier, made experiments which showed that vibrations can be transmitted along a copper wire and rendered visible at the distant end on a rotating blackened drum. The free end of the wire was attached to a piece of copperfoil fixed at its base and provided with a point which left a clear trace on the drum when the distant end was attached to, say, a vibrating tuning-fork. By connecting such an arrangement with different instruments and varying the players also, M. Cornu has ascertained the form and extent of vibration corresponding to each. The arrangement adopted by him was exhibited by Prof. Adams, and in conclusion he referred to a passage in Hooke's "Micrographia," which clearly showed that he was aware of the facility with which sounds can be transmitted by solid bodies.—Mr. W. H. Preece described some experiments made in September of last year, by Mr. A. W. Heaviside and Mr. Nixon at Newcastle-on-Tyne on this subject, from which they conclude that the method might certainly be applied with success to the transmission of speech within a building. They find that a No. 4 wire gives the best results. The terminals were wooden discs about $\frac{1}{8}$ in. thick, and to these the wire was attached "end on," but speech could be distinctly heard by laying such a disc on any intermediate point of the wire. When the wire was particularly still speech was audible up to 200 yards.—Mr. G. W. von Tunzelmann then read a paper on the production of thermo-electric currents in wires subjected to mechanical strain. The wire, of iron, steel, or copper, was stretched vertically between two cans which could be maintained at different temperatures. It was fixed in the base of the lower can and held in the upper one by a clamp attached to the shorter arm of a lever, to the longer arm of which the stretching weight was applied. The free ends of the wire were joined to copper wires which led to the Thomson galvanometer, these junctions being covered with cotton wool. He has succeeded in reconciling the contradictory conclusions arrived at by Sir W. Thomson and M. Le Roux; whereas the former only used moderate strains, the latter worked near the breaking limit, and the author finds that if the weight be gradually increased the direction of the current changes, and hence these two authorities found the currents to flow in opposite directions. A great number of experiments were made, and from them it is evident that on applying a strain the deflection does not immediately attain a maximum, but it gradually rises for about eight minutes, and then gradually falls, attaining a stationary point at the end of about twelve minutes.—Prof. Adams then exhibited a simple arrangement for projecting Lissajous' figures on to the screen which has been made by his assistant, Mr. Furze. It consists of two strong straight steel springs, fixed in separate heavy iron frames, the one horizontally and the other vertically. The latter carries at its end a double convex lens and the former carries a black disc perforated with a small hole and is so mounted that its length may be varied as required. If now the disc be placed before the lamp and the point of light be focussed on the screen by means of the lens on the vertical spring, the two springs may be caused to vibrate and the spot will describe a figure corresponding to their relative rates.—Dr. Guthrie exhibited an experiment to show the behaviour of colloids and crystalloids in relation to electrolysis. A solution of gelatine was coloured with litmus, made acid and mixed with sulphate of soda; two platinum poles of a 6-cell Groves' battery were then immersed in it and the gelatine was allowed to set. The mass became comparatively clear round the positive pole and red and blue clouds were formed which met across a space of about 1½ in. in three-quarters of an hour. The relative advance of the ions was indicated by the brightening of the litmus round one pole and by the blue coloration produced at the other.

Chemical Society, April 4.—Dr. Gladstone, president, in the chair.—A lecture "On the Application of the Microscope to some Special Branches of Chemistry" was delivered by Mr. H. C. Sorby, F.R.S. The lecturer confined his discourse to the application of the microscope for determining the refractive indices of liquids and solids. An object is placed on the stage of a microscope and the focus adjusted accurately; on covering the object with a plate of some refracting substance, the object will be invisible; to bring it again into focus the body of the microscope must be moved further out. If this distance be "d" and the thickness of the plate be T, then the index of refraction $= \frac{T}{T-d}$. This distance can be measured either by a scale and vernier attached to the body of the microscope or by graduating the head of the screw which works the fine adjustment. The lecturer then described the various methods by which the two quantities T and d could be practically measured to $\frac{1}{1000}$th of an inch; the curious and diversified images seen by observing with a microscope a circle or a grating through transparent plates of various substances were then explained. Minerals having no double refraction are unifocal, *i.e.*, both systems of lines in a grating can be seen at the same focus. Minerals having double refraction are bifocal, *i.e.*, only one system of lines can be seen at one focus, a new focus having to be found in order to see the lines at right angles to the first set. This method has enabled the author to identify various minerals in sections $\frac{1}{500}$th inch thick and $\frac{1}{100}$th inch in diameter. Thus in a dolerite $\frac{1}{400}$th inch thick, a zeolite, labradorite, calcite, and augite were identified with almost absolute certainty. In sections of shells $\frac{1}{1000}$th of an inch thick calcite can be easily distinguished from arragonite. In conclusion the lecturer referred to the connection between the indices of refraction and chemical composition; the data are defective at present, but several points have already been made out; thus of two minerals having similar compositions, but one containing calcium and the other one of the alkalies, the first has a higher index of refraction; a lime garnet on the other hand has a lower index than a precious garnet which contains iron instead of calcium.

Linnean Society, April 4.—W. Carruthers, F.R.S., vice-president, in the chair.—There was exhibited by Dr. H. Trimen the base of the stem of the Water Hemlock (*Cicuta virosa*, Linn.) in its floating winter state, obtained near Yarmouth. This was well figured in the *Phil. Trans.* last century, but since has seldom been referred to by botanists.—Mr. G. Murray showed under the microscope specimens of growing Saprolegnia, exhibiting terminal and interstitial oogonia.—A paper on some minute hymenopterous insects, by Prof. J. O. Westwood was, in his absence read by Mr. McLachlan. This contains descriptions of the following new forms: *Mymar taprobanicus*, *M. wolastonii*, *Alaptus excisus*, *Oligosita subfasciata*, *O. stanforthii*, *O. nodicornis*, and *Trichogramma erosicornis*. All singular insects alike interesting structurally and as regards habits, &c.—A short notice was made by Mr. M. C. Cooke on a collection of fungi from Texas, made by Mr. Ravenel. Adding all other recorded species the series shows that much yet remains unknown in the mycologic flora of what probably is one of the richest States of the Union.—The Secretary read some remarks on the peculiar properties ascribed to a fungus by the Samoans, by the Rev. Thos. Powell. The natives name it "Limamea"; specimens of which have been forwarded to the Rev. M. Berkeley for identification. It destroys their bread-fruit trees and the Chestnut (*Inocarpus edulis*). An antidote to its ravages is said to exist in the liliaceous plant *Crinum asiaticum*, which the natives grow between the trees liable to be affected.—The following gentlemen were elected Fellows of the Society:—Frederick Manson Bailey, Dr. Archibald Hewan, George Payne, jun., and James R. Reid.

Zoological Society, April 2.—Prof. Newton, F.R.S., vice-president, in the chair.—A communication was read from the Marquis of Tweeddale, F.R.S., containing the seventh of his contributions to the ornithology of the Philippines. The present paper gave an account of the collection made by Mr. A. H. Everett in the Island of Panaon.—Mr. A. G. Butler, read descriptions of new Lepidoptera of the group Bombycites in the collection of the British Museum.—A communication was read from M. E. Oustelet, containing the description of a new species of cassowary, from New Guinea, proposed to be called *Casuarius edwardsi*.—A communication was read from Mr. F. Nicholson, F.Z.S., containing the description of an apparently new species of American pipit from Peru, which he proposed to call *Anthus peruvianus*.—Prof. A. H. Garrod, F.R.S., read some notes on the placentation of *Hyomoschus aquaticus* as observed in the pregnant uterus of a fresh specimen of this animal recently examined.

Victoria (Philosophical) Institute, April 1.—A paper on modern geology and its bearing on the antiquity of man, was read by Prof. Birks, of Cambridge.

Institution of Civil Engineers, April 9.—Mr. Bateman, president, in the chair.—The paper read was on the embankments of the River Thames, by Mr. Edward. Bazalgette, Assoc. Inst. C.E.

EDINBURGH

University Chemical Society, March 13.—Mr. W. Inglis Clarke, B.Sc., vice-president, in the chair.—A paper was read by Mr. Adrian Blaikie on the salts of trimethylsulphine, containing the results of a joint investigation carried on by Prof. Crum-Brown and himself. They find that the oxalate of trimethylsulphine crystallises in clear hydroscopic plates with one molecule of water of crystallisation, $\{(CH_3)_3S\}_2C_2O_4 + H_2O$. On heating, the salt at 110° C. gives off its water of crystallisation, and at 140° gives off sulphide of methyl, leaving pure oxalate of methyl, $\{(CH_3)_3S\}_2C_2O_4 = (CH_3)_2C_2O_4 + 2(CH_3)_2S$. The sulphide of trimethylsulphine, obtained by mixing equal quantities of sulphydrate and oxyhydrate of trimethylsulphine, can only be obtained in a solution which when evaporated over phosphoric anhydride in an atmosphere of coal gas, decomposes, after a certain strength of solution has been reached, into sulphide of methyl, $\{(CH_3)_3S\}_2S = 3(CH_3)_2S$. The hyposulphite of trimethylsulphine is obtained either by oxidation of the sulphide or polysulphide of trimethylsulphine. It crystallises in clear hydroscopic four-sided prisms with one molecule of water of crystallisation, $\{(CH_3)_3S\}_2S_2O_3 + H_2O$. This salt has all the characteristics of an alkaline hyposulphite. On drying over phosphoric anhydride it gives off its water of crystallisation, and on heating the anhydrous salt at 137° C. it gives off 23·5 per cent. sulphide of methyl, leaving a white crystalline substance, soluble in water, alcohol, and ether, which is at present under investigation.—A paper was also read by Mr. John Treharne, M.B., C.M., on some phenomena observed in the cooling of fats.

PARIS

Academy of Sciences, April 15.—M. Fizeau in the chair.—The following among other papers were read:—Sun-spots and magnetism, by M. Faye. Replying to Prof. Piazzi Smyth's question (NATURE, vol. xvii. p. 220), M. Faye says:—1. The periods 10·45 years for the needle, 11·11 for the spots, have been well determined by Mr. Broun and M. Wolf respectively. 2. The[illegible] phenomena are not related. 3. A combination of favourable circumstances, reproduced every 176 years, has led to [illegible] in their connection. 4. These temporary concomitances are not absolutely rare in the history of sciences.—On a new compound of palladium, by MM. Sainte-Claire Deville and Debray. This relates to an ammoniacal sesquichloride of palladium, obtained by causing chlorine solution to act in the cold state on yellow chloride of palladamine. One analysis of it gave: palladium, 42·6; chlorine, 43·5; ammonia, 12·9.—Experiments tending to imitate various forms of foldings, contortions, and ruptures met with in the earth's crust (continued), by M. Daubrée. A thin layer of an adhesive colouring matter is applied to the surface of a distended balloon of vulcanised caoutchouc. On letting some of the air escape the coated portion forms a protuberance with regular and parallel wrinkles in certain directions; and M. Daubrée finds like phenomena in the earth's crust.—On the annual temperature of the air, the earth, and the water, in the Jardin des Plantes of Montpellier, according to twenty-six years of observations, by M. Martini. The mean annual temperature (of the air) is 13·42°; at Paris and Montsouris Observatories it is 10·67° for the same twenty-six years. The mean annual temperature at 0·10m. depth in unsodded ground is inferior to that of the air (about 2°) if only morning observations are taken; but from observations morning and evening they are nearly the same (ground, 14·65°, and air 14·11°, in the year 1863). The mean temperature of the subterranean sheet of water is 12·77°.—Report on a memoir by M. Jobert relating to aerial respiration of some Brazilian fishes. M. Jobert has found several fishes in the Upper Amazon, having two modes of respiration, one by the gills, the other by the alimentary canal, swallowing air and evacuating by the anus a gas which has more CO_2 and less O than air has. The intestine has a number of filiform appendices composed of blood vessels, which doubtless absorb some of the swallowed oxygen. In other fishes the gas returns by the mouth instead of the anus. In others the swimming-bladder (which has numerous blood vessels in its walls) takes the place of the lungs.—On the equivalent of gallium, by M. Lecoq de Boisbaudran. From calcination of the alum and calcination of the nitrate the mean obtained for the equivalent is 69·865. This agrees closely with a theoretical number got for a body between aluminium and indium.—On the mode of formation of the meteoritic breccia of Santa Catharina, Brazil, by M. Meunier. Four phenomena are traced:—1. Shattering of the metallic iron, and accumulation of the fragments with spaces between. 2. Penetration of sulphuretted hydrogen into these spaces, producing sulphur, and a mixture of pyrrhotine and graphite. 3. Mechanical crushing of the mass. 4. Production of new graphitous matter filling the fissures of the second formation.—On the dissociation of hydrate of chloral, by MM. Moitessier and Engel. From experiment they find that the tension of the vapour of the substance, when boiling, is superior to atmospheric pressure, hence they infer dissociation of the hydrate between 78° and 100° as affirmed by M. Wurtz.—On a rare form of the hepatic organ in worms, by M. Chatin. In a nematoid of the group of *Agamonema*, Dies, an exterior glandular mass is developed round the middle intestine.—Experiments proving that pure urea never causes convulsive disorders, by MM. Feltz and Ritter.—On two rainbows with opposite curvature, by M. Faraguet. This was observed at Agen, on April 8. The bows formed a figure like *x*.—M. Tommasi presented a new system of relays for long submarine cables.
